The basic oven

Flexible.
Get-attable.
The basis for 7 different chromatograph oven systems.
To go with 4 detectors—ECD, FID, Thermionic or Katharometer.
To make 10 detector systems.
To give you precisely what you want.
Sensitivity. Versatility.
Add the automatic solid injection system or the Curie Point Pyrolyser or any one of a wide range of accessories and you have one of the world's really great chromatographs. For routine, research or computer controlled analyses. The Pye Series 104.
Write or telephone for details today.

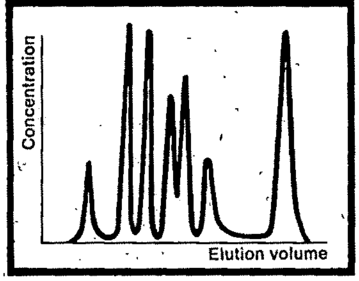
Sephadex®

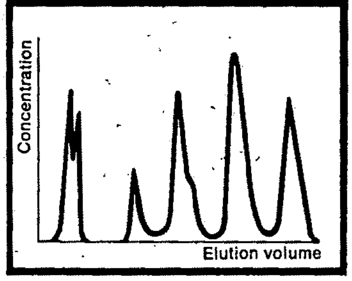
Partition chromatography



Separation of esterified catecholamine metabolites by partition chromatography in 1,2-dichloroethane: methanol (7:3).

(Anggard, E., et al., J. Chromatog. 50 (1970) 251-259)

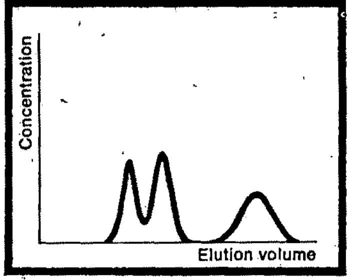
Gel filtration



Gel filtration of triglycerides and fatty acids in chloroform.

(Adapted from Downey, W.K., et al., J. Chromatog. 46 (1970) 120—124. Reproduced by kind permission of the Authors and the Publisher.)

Adsorption chromatography



Separation of oestrogens by adsorption chromatography in distilled water.

(Van Baelen, H., et al., J. Chromatog. 30 (1967) 226—227. Reproduced by kind permission of the Authors and the Publisher.)

Sephadex® LH-20

in organic solvents and aqueous solutions

Sephadex LH-20 is a lipophilic derivative prepared from Sephadex G-25 by hydroxypropylation. It is supplied in bead form (dry particle size 25—100 μ) as a dry, free-running powder which swells in water and polar organic solvents. The degree of swelling decreases with decreasing solvent polarity. Although introduced as a medium for gel filtration in organic solvents Sephadex LH-20 has rapidly become established as a medium for other types of chromatography which depend on partition and adsorption effects.

Sephadex LH-20 is used in polymer fractionation, lipid and steroid separations, aliphatic and aromatic hydrocarbon separation as well as in a host of diverse applications.

Special solvent resistant columns are available.

Interference of Electromagnetic Waves

A. H. COOK

This fundamental account of the aspects of interference that are of the greatest practical importance in spectroscopy, optics, mechanical engineering, and radio astronomy is written for research workers, teachers, and post-graduate and honours-year undergraduate students. The treatment is based mainly on the idea of coherence of electromagnetic fields and an attempt has been made to give a unified account of both optical and radio interferometers. Laser and radio-astronomical sources have led to much simpler accounts of interference methods. These developments and the use of interferometers for precise measurements in engineering and optical spectroscopy are emphasized. 90 text figures £5 *International Series of Monographs on Physics*

DOMINVS ILLVMINATIO MEA

OXFORD UNIVERSITY PRESS

ADVANCES IN BIOPHYSICS

Edited by Masao Kotani

The new annual series that concentrates on the theoretical aspects of the latest developments in biophysics. Published under the scientific direction of the Biophysical Society of Japan, each volume presents the year's most important research results by leading biophysicists from Japan and other countries. As reviewed in *Science*: "In all cases the papers are amply illustrated and clearly presented . . . As many of the authors chosen for this and forthcoming volumes are important contributors to their respective fields, the series promises to be an interesting addition to the biophysics literature."

Volume 2

Crystal Structure of Tropomyosin. Electrogenic Sodium Pump. One-Electron and Two-Electron Transfer Processes in Enzymic Oxidation and Reduction. Phase Transition in Membranes with Reference to Nerve Excitation. Stochastic Theory of Reaction Kinetics.

230 pages. Illus. July 1971. $12.50

Volume 1

The Lateral-Line Organ of Shark as Chemoreceptor. Ribonuclease T_1 — Structure and Function. Polymerization of Flagellin and Polymorphism of Flagella. Spin Changes in Hemoproteins.

193 pages. Illus. 1970. $11.50

Your continuation order for the series ensures automatic shipment of each new volume immediately upon publication.

ATOMIC AND MOLECULAR RADIATION PHYSICS

by **L. G. Christophorou**, *Oak Ridge National Laboratory and the University of Tennessee.*

A coherent picture of many apparently different areas of research in atomic and molecular photophysics and atomic and molecular collision processes, this work discusses the relevance and importance of these fundamental studies, at atomic and molecular level, to radiation science and biology. It covers at a fairly fundamental level the recent research on atoms and molecules (small and complex), obtained both by photophysical and particle collision processes, and discusses the importance of such studies to the understanding of the interaction between radiation and matter and biological action of molecules.

(*Continued overleaf*)

Aspects of Terpenoid Chemistry and Biochemistry

Proceedings of the Phytochemical Society Symposium, April 1970

edited by T. W. Goodwin

June 1971, xiv+442 pp., £8.50.

This, the proceedings of the second Phytochemical Society symposium on terpenoids, reveals the extensive progress which terpene chemistry, biochemistry and biology have made in the past few years and complements the first symposium. The recent developments in the biosynthesis, metabolism and function of plant terpenes are presented by international experts.

As with previous volumes in the series, this is intended for research workers and graduate level students in the field.

Neurotransmitter–Receptor Interactions

D. J. Triggle

June 1971, x+610 pp., £9.00

This text discusses the molecular basis of neurotransmitter-receptor interactions from a multidisciplinary standpoint, for an effective understanding of the actions of neurotransmitters will require collaboration between disciplines. Emphasis has been placed on two broad areas, into which the author believes knowledge of neurotransmitter-receptor interactions must be incorporated; these areas are the regulatory control of macromolecules and membrane structure and function.

As a result of the emphasis on interdisciplinary cooperation, the book should not only be of value to workers researching drug-receptor interactions, but also as a guide to scientists from other disciplines who wish to enter this field.

Biochemical Society Symposium Number 32

The Biochemistry of Steroid Hormone Action

edited by R. M. S. Smellie

June 1971, x+174 pp., £3.50.

Contents: Estrogen action: a study of the influence of steroid hormones on genetic expression. Interaction of steroid hormones and histones. Steroid hormones, ribonucleic acid synthesis and transport, and the regulation of cytoplasmic translation. Steroid hormones and enzyme induction. The effect of steroids on the transport of electrolytes through membranes. Androgen stimulation of prostatic cation-dependent ATPase. Hormone-receptor interaction as a guide to biochemical mechanism. Author index. Subject index.

Ecology of Leaf Surface Micro-organisms

Proceedings of an International Symposium held at the Universty of Newcastle-upon-Tyne, September 1970

edited by T. F. Preece and C. H. Dickinson

June 1971, xviii+640 pp., £9.00

These proceedings are a unique presentation of the current state of knowledge on various aspects of leaf surface phenomena, especially their microbiological, chemical and physical characteristics.

As well as contributions from a large number of international experts, this volume contains recorded discussions, many of which will be as valuable as the papers in stimulating further work and in revealing gaps in our knowledge. Research workers and graduates in botany, agriculture, horticulture, microbiology and general biology at any level will find the papers and discussions of value and interest.

Gustation and Olfaction

An International Symposium, Geneva, June 1970

edited by G. Ohloff and A. F. Thomas

June 1971, x+276 pp., £4.00

This symposium was attended by chemists, biochemists, physiologists and those working in the perfume and flavour industries. These leading specialists were able to present original ideas and conclusions, which will greatly assist all researchers in this field. A significant coverage is given of the relationship between behaviour and taste or smell in both insects and mammals (including man). Several aspects of molecular structure in relation to odour and taste and particularly of stereochemistry are also investigated. A stimulating discussion followed during which varied opinions on present-day and future progress were expressed, a summary of which is reproduced in this book.

MANUFACTURERS OF
ASTRONOMICAL, SCIENTIFIC
and INDUSTRIAL EQUIPMENT

If you work with instruments where a high degree of accuracy is vital, an optical component that falls short of the specified performance costs time and causes frustration. Our business and pleasure is to produce components of the highest optical quality, or lower qualities if desired.

Foremost in the first category are our Fabry-Perot etalon plates; diameters up to 150 mm, with matching accuracies to better than $\lambda/200$. (We can supply standard 60 mm diameter plates from stock.) Solid etalons, plane-parallel plates, resonant reflectors, and super-flats to $\lambda/200$ are other examples of our more sophisticated production range.

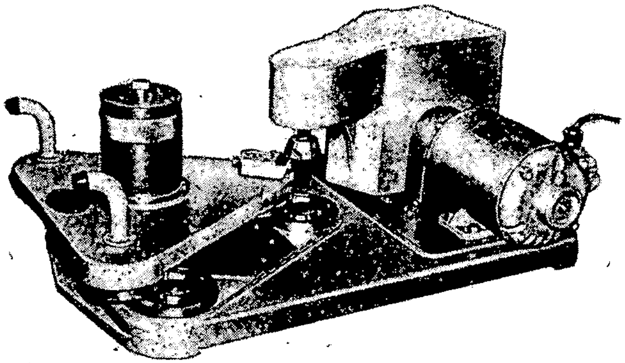
We make $\lambda/20$ optics for astronomical purposes, including all the conic sections—both on-axis and off-axis—and objective prisms, Schmidt plates ($\lambda/10$) and plane parallel windows. Outside the normal astronomical range, we will make almost any on-axis or off-axis conic (including grazing-incidence surfaces) to accuracies which constitute the present limits of optical skill. Our handwork department offers a specialized service in the production of prisms and small optics of all types to the most demanding specifications. Our craftsmen will produce almost any optical component you may specify in glass, silica or glass ceramic, and certain crystals.

It is our desire to provide the type of service and collaboration essential to so many research projects, and we invite your enquiries which will be given our prompt and careful attention.

CUTROCK

CROFT PARALLEL GRINDING MACHINE (MOTOR DRIVEN)

For precision grinding of thin sections and fossils



The travelling carriage of the machine moves in a circular track over the grinding plate controlled by steel balls running in precision machined tracks. Mounted in the centre of the carriage is a metric micrometer which houses the specimen holder. When the carriage is in the grinding position as illustrated, the micrometer can be adjusted until the specimen is in contact with the grinding plate, at this point the reading should be taken and then the amount to be ground off should be set on the micrometer. The specimen holder will lift by this amount and as the machine grinds the holder will return to its setting position, which once reached will stop any further grinding of the specimen even if the machine continues to run.

Grinding plates can be supplied in zinc, copper, cast iron, glass or lead.

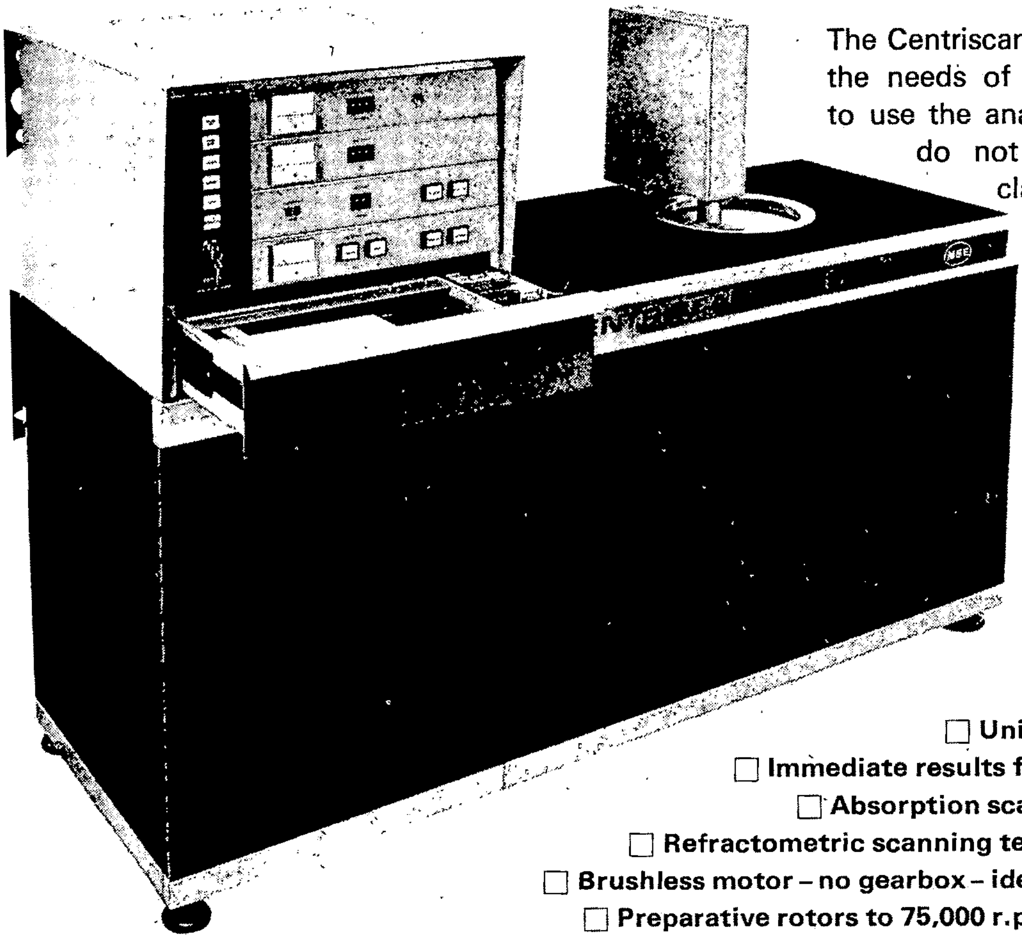
an ANALYTICAL ULTRACENTRIFUGE
with INTEGRAL SCANNER and RECORDER
plus PREPARATIVE FACILITIES

MSE CENTRISCAN 75

(and all at a price you can afford)



The Centriscan 75 meets, at relatively low cost, the needs of the many scientists who wish to use the analytical centrifugal technique but do not require the full facilities of a classical Analytical Ultracentrifuge. However, with recording of the absorbance of up to four samples at a time, the Centriscan 75 is capable of work of the highest precision, even on submicrogram quantities – work that was previously possible only with much more expensive equipment. In addition, the 75,000 r.p.m. preparative capability gives unique versatility.

- ☐ **Unique optical system**
- ☐ **Immediate results from direct traces – no cameras**
- ☐ **Absorption scanning down to 254nm**
- ☐ **Refractometric scanning technique giving Schlieren traces**
- ☐ **Brushless motor – no gearbox – ideal for equilibrium runs**
- ☐ **Preparative rotors to 75,000 r.p.m. – 500,000 x 'g'**

"*Must reading* for any lab director contemplating computerization . . ."

CLINICAL LABORATORY COMPUTERIZATION

By Arthur F. Krieg, Thomas J. Johnson, Jr., Clement McDonald, and Ernest Cotlove

The most highly acclaimed text yet published on computerization for clinical laboratories:

". . . must reading for any lab director contemplating computerization, and should be the first book he picks up on the subject . . . The reading is fast, the approach direct, and computer jargon kept at a useful minimum. Probably worth the price of the book alone is the chapter listing 73 questions the lab director should ask a prospective vendor in requesting a proposal . . . a guideline for minimizing cost overruns while maximizing the chances for selecting the best system for a given type of laboratory operation.

"This is one book that fulfills its purpose and provides the laboratory director with an effective road map through the maze of computer claims and counterclaims."

—*Laboratory Management*

". . . offers all possible factual information to help pathologists, laboratory directors, technologists, and hospital administrators choose an efficient, economic, and reliable computer system."

—*Lab World*

"The authors even give lists of example installations so that the prospective user can get some honest opinions. Easily readable and full of useful information."

—*Computer Decisions*

132 pages. Illus. 1971. $8.50

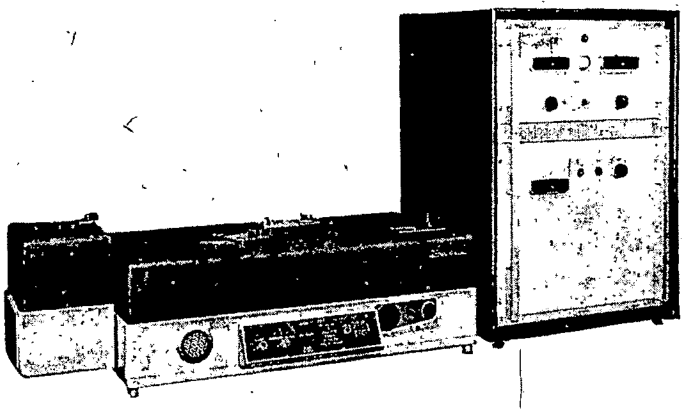
B&S Precision Instruments

The POLARMATIC 62 Automatic Spectropolarimeter



SOLE DISTRIBUTORS IN U.K. OF SCHOTT INTERFERENCE FILTERS

NOW O.R.D + C.D

We are pleased to announce that a Circular Dichroism attachment has been designed by the National Physical Laboratory and will shortly be available for this outstanding spectropolarimeter. Like the Polarmatic itself, this new device will once again open up new thresholds in biological research.

A great deal of engineering development has enabled us to offer this attachment to both new and present users of the O.R.D. instrument. For full details write to Dept. N.

We now have capacity for aluminising certain types of mirrors, at short notice.

For protein synthesis

A choice of three carbon-14 labelled amino-acid mixtures

Equimolar mixture for t-RNA
Specially provided for those studying acceptor-activity of t-RNA. An equimolar mixture of amino-acids-C14(U), each amino-acid having a specific activity accurately adjusted to 10mCi/mmol.
Code No CFB : 152

High specific activity mixture
A mixture of individually purified amino-acids uniformly labelled with carbon-14. The amino-acids are mixed in approximately the same proportions as in typical algal protein hydrolysate. The current batch has an isotopic abundance of carbon-14 of 87% (54 mCi/matom of carbon).
Code No CFB : 104

Purified Protein Hydrolysate – for economy
Protein hydrolysate-C14(U)—obtained by the acid hydrolysis of algal protein. The products of hydrolysis are extensively purified by ion exchange and paper chromatography to give an amino-acid content of not less than 95%. This is still the most economical protein labelling mixture available.
Code No CFB : 25

Sole supplier

The Radiochemical Centre is the only radiochemicals supplier able to offer you a readily available choice of products in this field. If you are interested in protein synthesis (or any other application of radiochemical products) please write for further information.

SALMON AND TROUT

A Resource, its Ecology, Conservation and Management

Derek H. Mills

Exploitation and pollution; hydro-electric development and erosion; just a few of the factors which affect the salmon and trout fisheries. So what of the future, when without the continued and enlightened efforts of man, the exploiter and polluter, there will be none.

Salmon and Trout is *the* book for anyone associated or interested in the present state and future development of the salmonid industry. Containing all the essential knowledge for the study, conservation and management of game fish, including a summary of the development of the high seas salmon fishery and methods for regulating stocks in home waters—it is a must for the scientist and layman alike.

372 pages lavishly illustrated £4.00

PL-1 PROGRAMMING IN TECHNOLOGICAL APPLICATIONS

by **Gabriel F. Groner,** The Rand Corporation, California

Describes how to write Programming Language One computer programmes for solving technical problems. Motivates the engineer, scientist, or student by introducing him to programming early in the book, then expanding his skills through numerous relevant examples and exercises at the end of each chapter.

This unique water still is in use in a number of research establishments and hospitals where water of the highest purity is essential.

PRICE, complete with heater and all electrical equipment 230 volt (a.c. only)—**£45.00**

Obtainable only from

L. V. D. SCORAH, M.Sc.
(Manufacturer of the "SCORAH" Blowpipe)
44 NORTHFIELD ROAD, KINGS NORTON,
BIRMINGHAM, 30 021-458 1885

The SCORAH Automatic Electric all glass WATER STILL (patented)

Automatic Can be left on without attention. Heater current cuts off if water supply is interrupted, or inadequate or forgotten. When receiver (5 litres capacity) is full, current cuts off. When distilled water is drawn from receiver, the still resumes operation until receiver is refilled.

Purity Electrostatically charged condenser droplets can pick up fumes, dust and air-borne organisms from the laboratory atmosphere. The design of the receiver vessel ensures absence of such contamination.

Efficiency Heater of Scorah design and manufacture, consumption 1,700 watts, output 2.4 litres per hour (the full theoretical yield). Cost 3½d. per gallon at 1d. per unit.

Safety The heating element is out of contact with the feed water, thus eliminating danger from "live" water supply or electrolytic effects or "burn out".

Assembly No retort stands or clamps are required. The 2½-in. diameter ball joint gives a strainless set-up. Outlet cap on boiler for quick periodical drain-off of sediment. The still may be installed on a shelf or platform about 1 ft. above bench level near a sink and enclosed in a transparent plastic cover to keep out dust.
Phoenix heat-resisting glass. Interchangeable ground glass joints.

THE PHYSICS OF CLOUDS

R. B. MASON

This book has been rewritten and expanded to take account of research done up to the end of 1969, both experimental and theoretical, on the microphysical processes of nucleation, condensation, droplet growth, initiation and growth of snow crystals, and the mechanisms of precipitation release. Rain-making experiments are appraised and there are chapters dealing with radar studies of precipitating clouds and the electrification of clouds. It is both a textbook for the student and a reference book for the research worker, primarily for the atmospheric physicist, although it contains much of interest for those working on nucleation phenomena, crystal growth, and aerosol physics.
Second edition 40 plates 143 text figures £12

READINGS IN MOLECULAR BIOLOGY

Selected by Dr. W. B. Gratzer

A topical review which puts molecular biology research under the microscope

The book is a selection of over 60 articles describing the significant experiments and advances in molecular and cell biology, virology and biochemistry during the past year. The reports first appeared in *Nature* during 1969 and 1970 as weekly contributions by the Molecular Biology, Cell Biology and other specialist correspondents to the journal. They take the form of short and lively reviews of topics in a broad area of biological research and are the first contributions of their kind to the scientific literature in which scientists write critical appraisals of their colleagues' work.

The wide-ranging subjects they discuss are necessarily diverse and include

nucleic acids
membranes
replication
enzymes
cells
techniques

The book will be of value to the research worker as a record of progress in his field, and to the third year undergraduate as a comprehensive introduction to the changing pattern of molecular biology.

SPECIAL OFFER

By special arrangement with the publishers, Macmillan and Co. Ltd., *Nature* is able to offer its readers copies of READINGS IN MOLECULAR BIOLOGY at the special rate of £1 (inc. p. & p.). If you wish to place an order for the book, please complete the form below and return it with your remittance.

(American distributor M.I.T. Press)

Please send me................copy/copies of READINGS IN MOLECULAR BIOLOGY at £1 net each.

COMPLEX VARIABLE METHODS IN ELASTICITY

by **A. H. England,** *Department of Theoretical Mechanics, University of Nottingham*

Deals with the plane strain and generalized plane stress boundary value problems of linear elasticity; these problems are formulated and solved using complex variable theory. In this book the basic representation of the displacement field in terms of functions of a complex variable is derived directly from the equations of elasticity. Also the three basic methods relying on series representation, Cauchy integral representation, and the solution via continuation, are all described in detail. Worked examples and sets of problems are included.

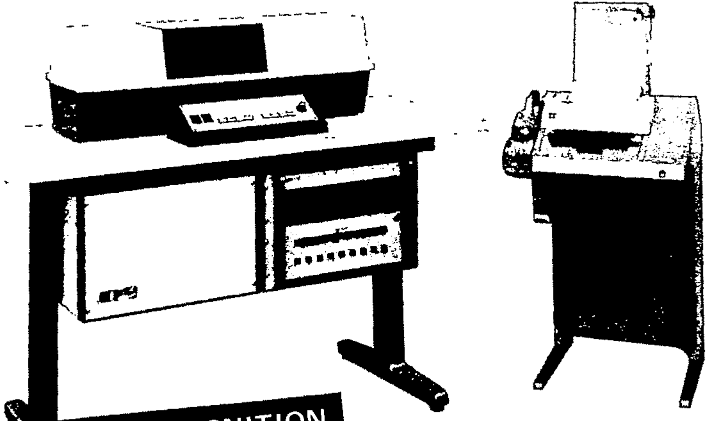
the *VERY BEST* high-quality image processing system for your dollars

- RASTERS AND APERTURES TO 12.5 MICRONS
- ORTHOGONAL SAMPLING GRID
- PHOTOGRAPHIC DENSITY RANGE 0–3D
- DATA RATES TO 60 KC
- FORMATS TO 10" x 10" FLEXIBLE FILM
- GRAY LEVEL RESOLUTION: READ MODE – 256 PARTS
  WRITE MODE – 64 PARTS

REMOTE SENSING



PATTERN RECOGNITION

Photomation Mark II

An electro-mechanical high-speed, high-accuracy photographic digitizer and plotting system for image processing and/or generation. Operates on-line and can be computer-controlled, or interfaced directly to magnetic tape.

CONTOUR PLOTTING

Photoscan

An electro-optical drum scanner with high-accuracy, bidimensional position in micron range for rapidly digitizing photographic data on film negatives or positives. Typical scan time for 100 micron raster of 5" x 5" format is 5 minutes.

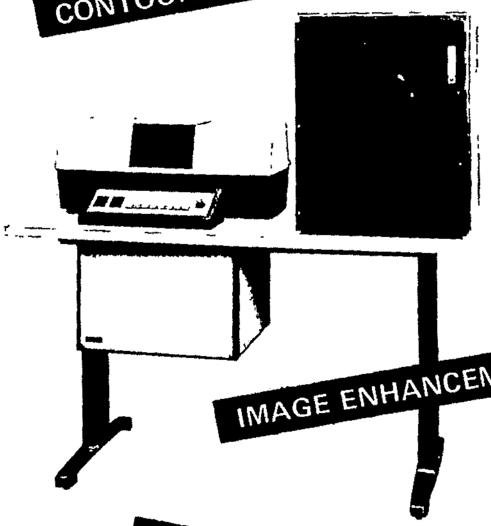


IMAGE ENHANCEMENT

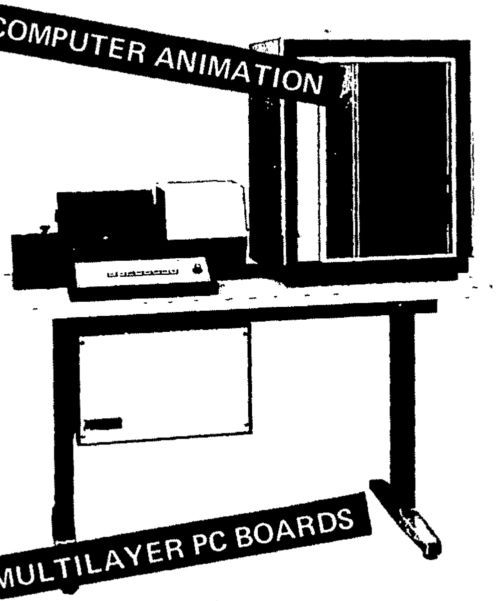
COMPUTER ANIMATION

MAP MAKING



X-RAY CRYSTALLOGRAPHY

Photowrite

An electro-optical high-speed digital film writing system. Digital information from magnetic tape or directly from a computer modulates the beam from a light source and exposes the film producing up to 64 repeatable gray levels. Typical reconstruction time for a 5" x 5" format at 100 micron raster is 2 minutes.

Rayleigh scattering—Caused by obliquely oriented uniform needles—SHAH (TIFR, Bombay)

Polyhalite—Recent polyhalite from Sebkha el Melah—PERTHUISOT (Paris)

Particles—Absolute determination of size and shape—CHENG and SUTTON (Department of Trade and Industry)

Norwegian sea—New crustal model—HINZ (Hannover) and MOE (Bergen)

Next Wednesday's issue will include

Myeloma proteins—Structural differences in hinge region of subclasses of γA myeloma proteins—ABEL and GREY (Denver)

Myofibrillar ATPase—Neural control in rat skeletal muscle—BULLER (Bristol), MOMMAERTS and SERAYDARIAN (Los Angeles)

Bacteriochlorophylls—Found in gliding filamentous prokaryotes from hot springs—PIERSON and CASTENHOLZ (Oregon)

Hemiplegia—Dysfunction of lower motor neurone associated with atrophy—McCOMAS, SICA, UPTON, AQUILENE and CURRIE (Buenos Aires)

Membranes—Evidence against hydrogen-calcium competition model for activation of electrically excitable membranes—EHRENSTEIN (Bethesda) and FISHMAN (Woods Hole)

Advances in Biomedical Engineering Volume 1

edited by R. M. Kenedi

July 1971, x+252 pp., £5.00

This new *Advances* series aims to present significant pioneer work of a wide range, from research to clinical and technological applications in this new multidisciplinary field. It will also provide a review of the existing state of the subject as well as presenting further additions to present knowledge.
The series will be of particular interest to clinicians, practitioners, teachers, researchers and students at all levels of medicine, biology and engineering. It will provide an invaluable source of reference and it is hoped that the material included will help to further applications and stimulate interest and research in this field.

Scientists and the Sea 1650-1900

A Study of Marine Science

Margaret Deacon

June 1971, xvi+446 pp., £5.50

During the past 30 years the oceans have become one of the principal areas of scientific exploration. However, little has been heard of the origins of marine science. This book traces its growth from remote beginnings in the ancient world, through the scientific revolution of the seventeenth century to the point reached late in the nineteenth century when it at last achieved recognition as an independent scientific discipline. 'Scientists and the Sea' takes a new look at the men who took part in the development of this science, including Robert Boyle, Robert Hooke, Sir Isaac Newton, Sir Joseph Banks, William Whewell and T. H. Huxley.

East African Mammals Volume 1

An Atlas of Evolution in Africa

Jonathan Kingdon

July 1971, x+446 pp., £12.00

This is the first of a three volume work. It has an introduction to the East African environment but deals mainly with the primates. Mammalian evolution is the central theme; but the work aims to be a comprehensive inventory, textbook and atlas as well. This volume relates existing knowledge of geography, vegetation and anatomy to mammology and to the evolution of the species. *East African Mammals* presents a broad background for the student of mammology and much new information about species. This contribution to the understanding of evolution on the African continent will be of interest to zoologists, naturalists, veterinary and museum workers, primatologists and paleontologists.

Methods in Microbiology Volume 5B

edited by J. R. Norris and D. W. Ribbons

July 1971, xiv+696 pp., £9.50

Contents
The disintegration of micro-organisms. Centrifugal techniques for the isolation and characterization of sub-cellular components from bacteria. Chemical analysis of microbial cells. Chemical extraction methods of microbial cells. Biphasic separation of microbial particles. Separation and purification of proteins. Zone electrophoresis of the separation of microbial cell components. Free-flow electrophoresis. Disc electrophoresis. Isoelectric focusing and separation of proteins. Reflectance spectrophotometry. Base composition of nucleic acids. Author index. Subject index.

Symposia Mathematica Volume 6

Published by The Italian National Institute of Higher Mathematics

July 1971, vi+396 pp., £7.30

Internationally known scholars have presented original, unpublished works on diverse scientific and mathematical questions. Functional analysis, evolutionary problems in the solar system, number theory, homological algebra, categorical algebra and algebraic topology are some of the broad fields covered in recent volumes. Mathematicians working directly with the theories discussed in these papers will find them valuable and interesting; physicists, astrophysicists and engineers will also find them useful for further scientific studies.

Pye Unicam has a new automatic enzyme analyser. This is what makes it tick.

It is the new Unicam AC61 Programme Delay Unit, which holds the reacting mixture in a spectrophotometer flow cell from 5 seconds to 5 minutes while the change in absorbance is measured.

The whole system – comprised of an automatic chemical processing unit, a spectrophotometer and a recorder – has been designed for versatility and precision at low cost.

The system is simple to operate. Programming takes only a few minutes. Sample and reagent volumes are controlled by preformed templates. No initial sample preparation is required.

Enzyme reaction rates can be measured and recorded completely automatically at speeds ranging from 12 – 60 an hour, while other chemical analyses can be completed at up to 120 samples an hour.

Above all, the system is backed by methods proved in the Pye Unicam Applications Laboratory and over 20 method sheets are currently available including LDH, CPK, SGOT and SGPT in serum.

Find out more about the Unicam Automatic Analytical System by telephoning or writing to Pye Unicam today.

World health looks to the life sciences . . .

Here is one of our contributions:

Is this the golden age of the life sciences? Recent and continuing research into the molecular anatomy of cells is piercing the mists that have shrouded the chemical basis and control of all living things for centuries. But scientists must have the tools, hence the MSE Super Speed 75 preparative ultracentrifuge. It meets every possible centrifugation requirement of the research scientist—whether it be for the highest g value (511,000 x g at 75,000 rpm with the 8 x 14ml rotor) the best possible combination of capacity and speed (e.g. 75,000 x g at 21,000 rpm with the 6 x 250ml rotor) or for the zonal technique for which the Super Speed 75 will accept all "B" type zonal rotors. Fully automatic, the Super Speed 75 incorporates all those features that scientists themselves, most exacting of people, have asked for.

POLARIZATION INTERFEROMETERS

Applications in Microscopy and Macroscopy

by **M. Françon** *and* **S. Mallick**, *both of the Laboratoire D'Optique, Faculté des Sciences, Université de Paris*

This monograph aims to present in simple language the fundamentals of polarization interferometers, their important applications and the latest developments in the field. As many non-physicists use these instruments a minimum of mathematics is used, and the emphasis is on the physical principles involved. Some technical details and numerical values are given to facilitate the setting up of the instrument in the laboratory. (*Wiley Series in Pure and Applied Optics.*)

Affinity and Matter

Elements of Chemical Philosophy 1800-1865

T. H. LEVERE

Affinity served as a unifying concept both within chemical theory and between chemistry and physics. It also played a crucial role in the development of the concept of matter, significant for the history of ideas. This book stresses these two aspects of affinity, relating them to each other and to their nineteenth-century intellectual background in science, philosophy, and religion. The development of the concept of affinity is introduced through Newton's legacy to the eighteenth century, and is then studied mainly through the contributions of major figures such as Davy, Faraday, Berzelius, Oersted, and Berthelot. 14 plates 7 figures £4.50

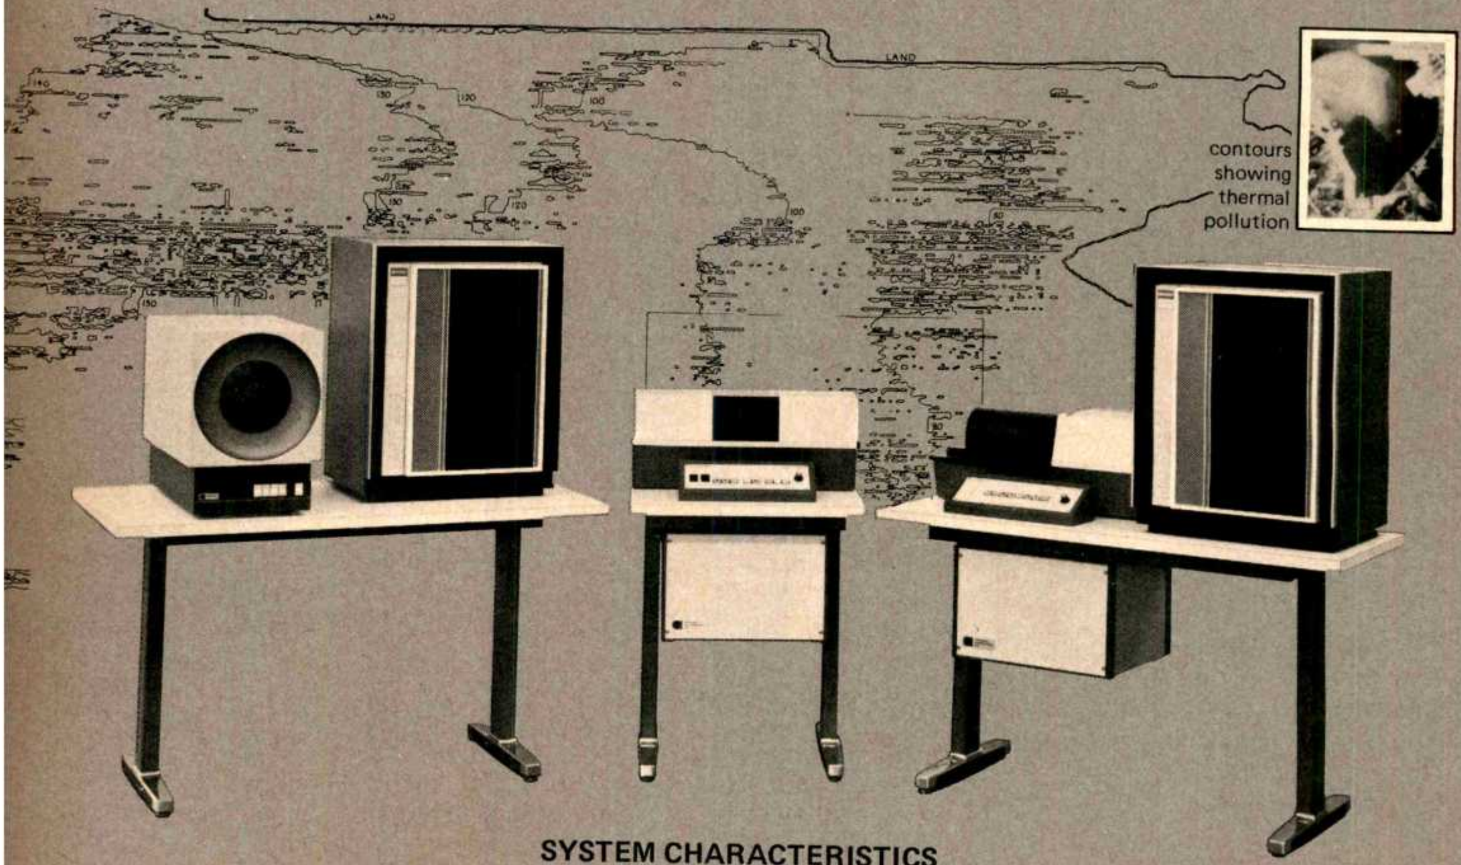
Photomation Mark I

The high-speed image processing system that extracts all your photographic data for storage and viewing

The P-1600 is fully integrated and can be computer-controlled, with a scanning microdensitometer on the input side and high-speed film writing unit on the output side, all supplemented by a tape transport and high-resolution CRT storage display



contours showing thermal pollution

SYSTEM CHARACTERISTICS

- Rasters and apertures to 12.5 microns
- Data rate to 25,000 picture elements per second
- Photographic display range from 0 to 3D
- Gray level resolution — 256 parts in read mode 64 parts in write mode
- Formats to 10" by 10" flexible film
- Color separation and reconstruction

Use the Mark-I with a small or large computer for:

- Remote Sensing
- Pattern Processing & Recognition
- Contour Plotting
- Industrial & Medical Radiology
- Electron Microscopy
- X-Ray Crystallography
- Particle Photography
- Image Enhancement
- Computer Animation
- Map Making

Input and output units of the Photomation Mark I system are obtainable separately and software is available. Contact our application engineers for further information today.

POLYMER

international journal on the science and technology of polymers and biopolymers

Polymer *is the international medium for the publication of original papers on the chemistry, physics and application of polymer research and on other disciplines which contribute to the development of polymer science.*

Polymer is published monthly to ensure the swift appearance in print of papers accepted for publication. All papers are scrupulously refereed and the journal is is guided by an editorial board of distinguished scientists whose activities cover all aspects of polymer research. Short communications, which deal with work that merits publicity before a full paper can be prepared, are published to keep readers abreast of current polymer research.

Annual subscription £15.00 ($37.50). From January 1st, 1972: £18.50 ($46.25). Pre-paid orders received before the end of 1971 will be accepted at the current rate of £15.

IPC Science and Technology Press Ltd,
IPC House, 32a High Street,
Guildford, Surrey, England.

TRANSFERABLE DRUG RESISTANCE FACTOR R

Edited by Susumu Mitsuhashi. Foreword by Bernard D. Davis

An up-to-date, critical study of resistance-transfer factors by one of the main contributors to their discovery and analysis — an achievement considered perhaps the most significant development in microbiology in the past decade.

In addition to presenting a complete review of the papers and reports of the many scientists engaged in R factor research, the book includes a large amount of previously unpublished data from the highly original investigations conducted by Dr. Mitsuhashi and his associates, with far-reaching implications in chemotherapy and antibody theory, as well as in questions of gene evolution and the urgent problems of lysogeny and latency in viral infection, including oncogenic viruses. *Contents:* Epidemiology of Bacterial Drug-Resistance; Epidemiology of R Factors; Genetic Properties of R Factors; Physiology of R Factors; Biochemical Mechanisms of R Factor Resistance; The Origin of R Factors. Name index. Subject index.

210 pages. Illus. 1971. $14.50

DRUG ACTION AND DRUG RESISTANCE IN BACTERIA

Edited by Susumu Mitsuhashi

Describes the action of macrolide antibiotics and lincomycin, the mechanism of bacterial resistance to these drugs, and the genetic and biochemical aspects of inducible resistance to macrolide antibiotics. The contributors to this volume include J. W. Corcoran, Bernard Weisblum, Hamao Umezawa, and other pre-eminent investigators in this field.

About 300 pages. Illus. August 1971. About $14.50

Announcing a new important Pergamon International Research Journal

Computers and Structures

Editor-in-Chief: Harold Liebowitz
School of Engineering and Applied Science
George Washington University
Washington DC 20006 USA

To be published bi-monthly - first issue September 1971

Size 247mm x 187 mm

Subscription rates:

one year	**£24.00** **$60.00**
two years (saving 10%)	**£ 43.20** **$108.00**

The objective of this new international journal is to provide a medium for the communication of information concerning the applications of computers (digital, analog and hybrid) and computer programs to the solution of scientific and engineering problems related to hydrospace, aerospace and terrestrial structures. The journal is intended to be of interest and utility to the researcher and practitioner in the academic, governmental and industrial communities. It is planned to publish technical papers and computer program papers in such relevant technical areas as structural mechanics, fluid mechanics and oceanography as utilized to establish structural loading, soil mechanics and foundations engineering, geology and geophysics and materials science and engineering including fatigue, creep, relaxation, fracture, stress corrosion, etc. Particular attention will be devoted to the practical engineering aspects of structural analysis, design and optimization.

Although the journal will publish authoritative papers on theoretical and experimental research and advanced applications of computer programs, it may also feature, when appropriate:

a *tutorial survey-types of papers reviewing some field or fields of computers and/or structures*
b *educational type of papers showing what computers are and how they could be used to assist the engineer in designing structures*
c *computer program described in sufficient detail as to be usable with minimum effort*
d *a special section entitled "Design Data and Methods" for contributions concerning computer-aided design of structures and structural elements and*
e *several pages devoted to reviews of books and papers published elsewhere, meetings, schedules and other information.*

MYOCARDIOLOGY

Recent Advances in Studies on Cardiac Structure and Metabolism

Edited by Eors Bajusz and George Rona

Selected papers from The Seminar on Preventive Myocardiology of the American College of Cardiology (June 1970) and the Third Annual (First American) Meeting of the International Study Group for Research on Cardiac Metabolism. A detailed, authoritative study of the most recent advances in investigative cardiology, ranging from functional-metabolic-structural interrelationships of heart in health and disease to the practical application of new research findings by preventive medicine.

Two volumes. About 900 pages. Illus. September 1971. About $45.00 the set

EXERCISE AND CARDIAC DEATH

Edited by Ernst Jokl and J. T. McClellan

A detailed clinical study of the phenomenon of sudden heart failure in seemingly healthy individuals. Presents extensive evidence showing that it is now possible to differentiate between the natural history of heart disease in patients with recognizable symptoms and those in whom the first overt symptom is terminal collapse. More than 30 eminent specialists document their clinical and laboratory experience with athletes, pilots, and others in sedentary and non-sedentary occupations, as well as with cases involving identical twins and successive generations in families. An authoritative source of basic clinical data and laboratory experimentation for cardiologists, pathologists, and internists. For every physician whose practice includes sports, aviation, military, insurance, or industrial medicine this volume provides information of critical importance to their diagnosis and treatment of cases of hidden heart disease.

183 pages. Illus. 1971. $11.50

Available in Europe from S. Karger

REACTIONS OF MOLECULES AT ELECTRODES

Edited by **Noel S. Hush,** *University of Bristol*

This book is concerned with the study of processes occurring at metal, semiconductor or insulator electrodes, an important topic which frequently overlaps with other often apparently unrelated fields. Specialists in other areas of chemistry are often unaware of the possible relevance of developments in the theory of electrode processes or of kinetic and thermodynamic data for such processes to their own fields, as the value of electrochemical methods in preparative chemistry has not yet been fully realized. The topics covered in this book are of importance not only to electrochemists but to research workers in many other branches of chemistry.

CUTROCK

MODEL VRS 150 LARGE SPECIMEN CUTTING MACHINE

Maximum cutting area 18″ × 9″

The machine is designed to cut specimens of rock, refractories, concrete and any hard materials requiring a diamond wheel as a cutting agent.

Using a 14″ diameter cutting disc the 9″ depth of cut is achieved by its reversing vice unit. The specimen is cut 4½″ deep with the first pass, is then turned through 180° and cut again, the second cut meeting the first, giving 9″ depth of cut. Specimens of 4½″ and under can be cut by one pass.

The machine is totally enclosed to contain all splash thus making it ideal for laboratory use. The illustration shows the machine fitted with the standard rock vice. A core vice is also available to cut both longitudinal and lateral cuts on cores up to 6″ dia × 18″ long.

Power feeds can be fitted if required.

Dimensions 54″ long 53″ wide 63″ high wt. 9 cwts.

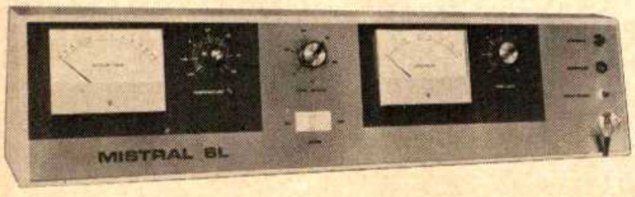
— and now we've added a smart new control panel and even more precise temperature control. Perfection!



The versatile carrying capacity of the MSE Mistral '6L', like its dependability, is proverbial in the world of temperature controlled centrifuging. But now the temperature system has been improved to give more accurate and rapid temperature readings of the actual contents of the centrifuge tubes. The modern ergonomically designed control panel is simple to use and gives at-a-glance information on centrifuging progress. Send today for Publication No. 476/B covering the Mistral range.

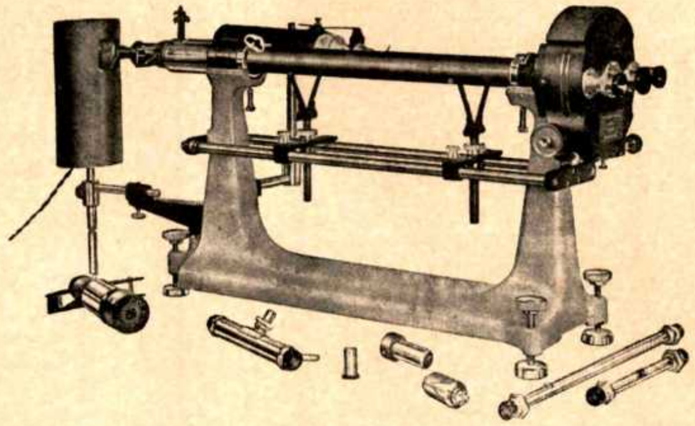
Many authors will have experienced delay in the receipt of reprints of articles published in *Nature* during recent months. Everything possible is being done to rectify the situation and the forbearance of those concerned is greatly appreciated.

Editor, *Nature*

BS **Precision Instruments**

Polarimeter Model A



This instrument gives the highest degree of accuracy with divided circle on glass reading to 0.01 degree.

Circle centre on ball bearings · Easily removable trough · Divided drum replacing verniers · Stationary observation telescope · Circle reader enlarging image of scale · Slow motion adjustment always in action · Suitable, with additions, for measurement of rotatory dispersion.

This polarimeter has been supplied in large numbers both in this country and abroad, and has always been acclaimed as being of advanced design and workmanship. Please ask for particulars "N".

We now have capacity for aluminising certain types of mirrors, at short notice.

CORONARY HEART DISEASE AND PHYSICAL FITNESS

Edited by O. Andrée Larsen and R. O. Malmborg

Fully covers the physiological and metabolic adaptations to exercise and training in normal man and in patients with coronary heart disease. Particular attention is given to the effect on the central and peripheral circulation, methods for measurements of physical fitness, training programs, and clinical studies evaluating the relation between physical inactivity and the risk of coronary heart disease.

About 284 pages. Illus. July 1971. $17.50

ELECTRICAL STIMULATION OF THE HEART IN THE STUDY AND TREATMENT OF TACHYCARDIAS

By H. J. J. Wellens

A detailed description of the techniques and procedures perfected for the evaluation and treatment of tachycardias in clinical trials at the widely respected cardiology clinic of the University of Amsterdam, directed by Dr. D. Durrer. Covers classification and diagnosis of tachycardias, emphasizing differential diagnosis between supraventricular tachycardias with aberrant conduction and ventricular tachycardias, theoretical considerations on tachycardias and methods used in this study, and detailed reports on studies in patients with atrial flutter, A-V junctional tachycardias, and tachycardias related to the pre-excitation syndrome.

MULTIVARIATE ANALYSIS:

Techniques for Educational and Psychological Research

by **Maurice M. Tatsuoka,** *University of Illinois*

Discusses multivariate statistical techniques useful in education and psychological research, including multivariate significance testing, multivariate analysis of variance, principal components analysis, discriminant analysis, and canonical correlation analysis. Develops the necessary matrix algebra in the context of statistical applications.

Practical, time-saving reference books for biochemists in teaching and research . . .

SELECTED PAPERS IN BIOCHEMISTRY

Series Editor: Denichi Mizuno

The twelve volumes in this series present a selection of the most significant papers published in biochemistry throughout the world, including early basic research as well as recent developments and discoveries. Each volume contains the full text, including original illustrations, of the seminal papers in a specific field of biochemistry of importance to modern study and research. An innovative concept in scientific publishing, designed specifically for advanced students, research workers, and permanent reference collections in schools and libraries.

Publication of the series begins July 1971 for completion by Spring 1972. Each volume will contain 250-300 pages. Price per volume: $12.50

Vol. 1: BACTERIAL GENETICS AND TEMPERATE PHAGE
Vol. 2: VIRULENT PHAGE
Vol. 3: CODING
Vol. 4: RADIATION BIOLOGY OF MICROORGANISMS
Vol. 5: RNA SYNTHESIS
Vol. 6: TRANSFER RNA
Vol. 7: PROTEIN SYNTHESIS
Vol. 8: ALLOSTERIC REGULATION
Vol. 9: ACTIVE TRANSPORT
Vol. 10: MITOCHONDRIA
Vol. 11: ENZYME MECHANISM
Vol. 12: PHOTOSYNTHESIS

Your continuation order for the series ensures automatic shipment of each new volume immediately upon publication.

COMPLEX PERMITTIVITY

Contributors: **B. K. P. Scaife, W. G. S. Scaife, R. G. Bennett** and **J. H. Calderwood.**

This book contains up-to-date reviews on three important aspects of dielectrics. The first is concerned with the molecular behaviour underlying the observed variation in the complex permittivity of dielectrics with frequency.

The second section is concerned with the work done in the high pressure field. Such work is capable of yielding important information concerning molecular behaviour, and is one in which research activity is increasing.

The third review is concerned with the various methods that have been devised to measure complex permittivity at frequencies below those requiring the use of wave guides.

THE ENGLISH UNIVERSITIES PRESS

St. Paul's House, Warwick Lane, London EC4P 4AH

Whither the Universities?

the Universities?

In the first issue of THES out on 15 October Sir Eric Ashby takes a long hard look at the present state and future of the universities, and warns of the possibility that increasing numbers of university and college students will be there who don't want to be there – Sir Eric terms them social conscripts – and flatly concludes that the academic establishment has no solution to offer.

Also in the first issue The Reverend Sir Herbert Andrew; and a feature on multi-disciplinary courses for scientists. Later, an interview with Sir Brian Flowers, and articles on: teaching applied mathematics – what the professors say; immunology – origins and advances; and the future of the Research Councils.

From 15 October – the THES: Friday's paper. 8p.

Unicam UV Spectrophotometers make light work

What does this mean to you? In research, results you can trust and repeat. In routine applications, error-free operation by the least experienced member of your staff.

When you come to Pye Unicam, even the selection of your UV spectrophotometer is simple. There is a choice of instruments broad enough to meet your every requirement and to match your budget, with a staff of experienced application specialists to back them up.

Just look at what is available . . .
SP500 Series 2 and **SP600 Series 2** quantitative single beam spectrophotometers, **SP700** for research, **SP1800** for low-cost double-beam operation, **SP3000** automatic digital instrument, **SP8000** for the ultimate in flexibility, and the **SP1300 Series 2** low-cost colorimeter.

Write or 'phone for free information today. That's simple too, isn't it.

We are Hooking the LKB 9000 to a COMPUTER

NOW the world-famous LKB 9000 Combined Gas Chromatograph-Mass Spectrometer has been linked to a computer system. The vast amounts of data supplied by the LKB 9000 can be processed quickly and with a minimum of manual effort. The computer data system can control mass scanning, data acquisition and display of the mass spectrum of any portion of the gas chromatogram. The program will allow on-line data acquisition from the LKB 9000 and simultaneous data handling without the use of internal mass spectra standards. Scans for the Combined GC-MS operations can be handled or scanned as often as you wish. Scan speeds for m/e 0—1000 of 3.5 seconds can be handled comfortably. Routine data will be available as a teletype readout and/or a plotted mass spectra with all background removed, and the data can be stored for future reference on either DEC tape or paper tape.

(Continued overleaf)

OXFORD BOOKS FOR STUDENTS

** Just published* *** Forthcoming*

* An Introduction to the Study of Man

J. Z. YOUNG

Professor of Anatomy, University College, London

The main aim of this book is to provide the basic facts of human biology. The agents controlling human activity are traced from their biochemical basis to the highest levels of consciousness. There are sections on heredity and reproduction, growth, intelligence testing, ageing, and population growth. Human evolution is traced from the origin of life to the beginnings of human culture. These facts provide background knowledge on many urgent problems, such as individual development, aggression and war, racial conflict, population control, and pollution. A main theme is that knowledge about the brain is revolutionizing our understanding of ourselves and the world. 256 line and half-tone illustrations. £6

** Lectures on Biostatistics

An Introduction to Statistics with Applications in Biology and Medicine

D. COLQUHOUN

Lecturer in Pharmacology, University College, London

This book is based on lectures given to medical science students with elementary mathematical knowledge and no statistical knowledge. The aim has been to include those topics which are of interest to laboratory workers, the discussion being based mostly on medical, physiological, and pharmacological problems. An attempt has been made to convey critical understanding while keeping the mathematics elementary, except in the appendices. 70 text figures £5·50 paper covers £2·75

* The Structure of Lebesgue Integration Theory

G. TEMPLE

Formerly Sedleian Professor of Natural Philosophy,
University of Oxford

This work provides an introductory account of Lebesgue integration for undergraduates, with many exercises and special emphasis on the motivation of the theory. The theory is reduced to its essentials—the techniques of 'bracketing' and of monotone sequences. The necessary theory of sets of points is simplified by using 'characteristic functions'. The Lebesgue-Stieltjes integral is briefly described. 4 text figures £3

ALGOL in Brief

A Short Practical Guide

J. F. RACTLIFFE

Senior Lecturer, Lanchester Polytechnic

In this rapid course of programming the scientific language ALGOL, the emphasis is on early program writing. The treatment is, as far as possible, informal. The style and approach is such that the student should be able to progress with only occasional help from his tutor. The general structure of programs is established in the opening pages by a detailed study of a number of simple programs; more advanced techniques are gradually introduced. 3 text figures paper covers 80p

Fungal Spores

Their Liberation and Dispersal

C. T. INGOLD

Professor of Botany, Birkbeck College, London

The remarkable range of structure in fungi is largely related to the production and liberation of spores. This book discusses the take-off of spores from a dynamic and experimental point of view and also considers the problems of further dispersal. Topics discussed include the aerobiology of fungal spores with special reference to methodology; dispersal by insects and the larger animals; seed-borne fungi; and the special features of dispersal in aquatic fungi. 8 plates 199 text figures £4

* Experimental Biology

A Practical Handbook

T. W. KIRBY and H. P. CLARK

This course follows the modern shift in emphasis from the intensive study of selective types to the extensive study of phenomena characteristic of life. The student is encouraged by experiments, realistic in their demands on apparatus, materials, and time, to conduct careful observation, accurate recordings and analysis, and interpretation over the whole field of modern biology to genetics and evolution. Spiral binding, laminated boards £1·25

* Introduction to Phase Transitions and Critical Phenomena

H. EUGENE STANLEY

Associate Professor of Physics,
Massachusetts Institute of Technology

This is the first book to be devoted to the interdisciplinary area of critical phenomena which, although having a long history, has only recently become an extremely active field of interest to physicists, mathematicians, chemists, and materials scientists. The simple mathematics makes the book useful supplementary material in undergraduate courses in thermodynamics. However, the book also provides a foundation for a short course for postgraduate students, and should prove essential for research workers entering the field. 10 plates 50 text figures £5 *International Series of Monographs on Physics*

* Stationary States
The Nature of Atoms
Bonds Between Atoms

ALAN HOLDEN

These three connected books were written for the Commission on College Physics in the United States to provide 'multi-level' instructional materials. Each is arranged in several sections of increasing sophistication in order to facilitate independent use as a textbook for existing courses and to offer bases for new kinds of courses. Their treatments bring together the viewpoints of physics, chemistry, and crystallography. SI units are used. Paper covers 55p, 75p and 85p respectively

Nitration and Aromatic Reactivity

J. G. HOGGETT, R. B. MOODIE, J. R. PENTON and K. SCHOFIELD

A summary of the present understanding of the nitration process for various types of nitrating systems, with special consideration of those systems in which mechanistic studies have established the identity of the agent through which nitration is effected.

The monograph will be used by graduate students and research workers in universities, institutes of technology and industry.

£5.00 net

The Principles of Chemical Equilibrium

K. G. DENBIGH, F.R.S.

The third edition of this well-known textbook provides a comprehensive guide to the thermodynamics of chemical equilibrium at undergraduate level. The first part of the book outlines the general principles of thermodynamics which are applied, in the second part, to systems in chemical equilibrium. The statistical mechanical approach is introduced in part three.

Cloth £4.40 net
Paperback £1.50 net

SYMPOSIA OF THE SOCIETY FOR EXPERIMENTAL BIOLOGY: 25

Control Mechanisms of Growth and Differentiation

Edited by D. D. DAVIES and M. J. BALLS

The proceedings of the twenty-fifth symposium of the Society for Experimental Biology held jointly with the British Society for Developmental Biology.

The symposium papers deal first with models and simple systems of development such as those found in bacteria and slime moulds. A series of papers then consider the formation and control of pattern in differentiation and development in more complex organisms. A discussion of the theoretical aspects of control mechanisms and of growth and differentiation is included at the end of the volume.

£8.00 net

A Guidebook to Biochemistry

M. D. YUDKIN and R. E. OFFORD

A new introductory text for students in schools, colleges and universities who are beginning courses in biochemistry, either by itself or as a background for work in biology, medicine, agriculture or pharmacology. It is based on Kenneth Harrison's successful *Guidebook to Biochemistry*, but has been completely revised and rewritten.

Cloth £3.20 net
Paperback £1.00 net

Modern Cosmology

D. W. SCIAMA

The exploration of the universe, as conducted by astronomers, cosmologists and physicists, is one of the greatest intellectual adventures of the mid-twentieth century. The author puts this work into perspective, summarizing present knowledge and theories, for senior undergraduate and graduate students and interested physicists.

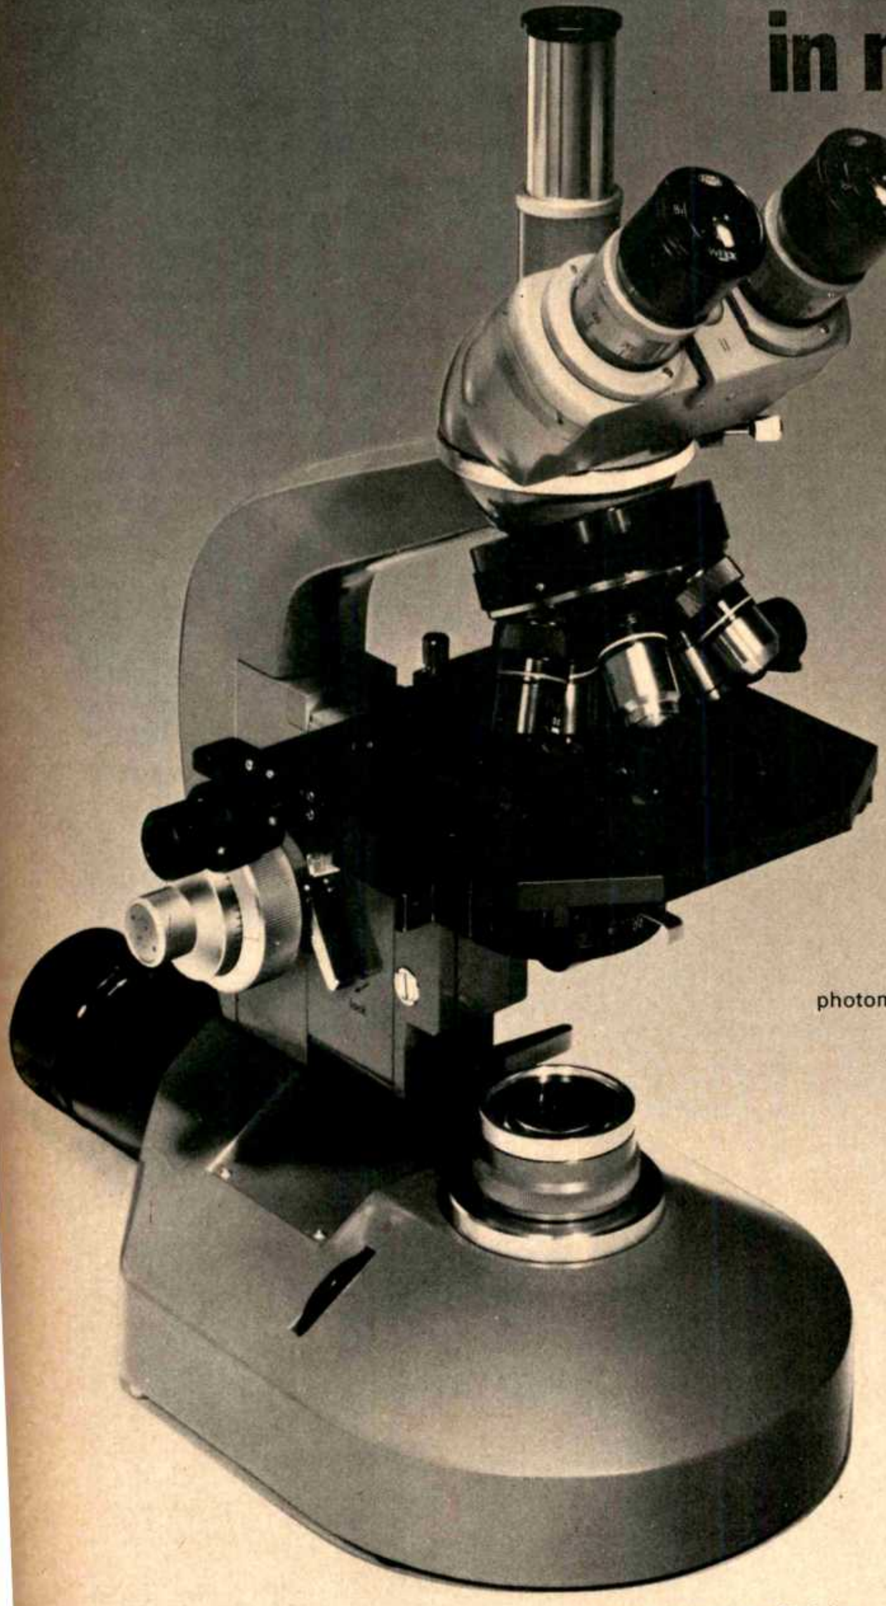
The microscope that works for you in multiple ways



This is the FHA, in its basic form a valuable addition to the field of microscopy. When full play is given to its versatility it becomes a super deluxe instrument — with enough interchangeable lenses to take you through practically any kind of research programs, a built-in illuminator, focusing down to as fine as 0.0005mm and heads that can deliver a superwide field of view or a full photomicrographic system. And the magnification range jumps right from 28× to 2000×. There are 8 models of the FHA, each one with a different eyepiece / objective / head / condenser arrangement, one just right for your application. With the standard turret mounted plan achromatic objectives you get super corrected components which make color and spherical aberration and field curvature almost non-existent, resulting in ideal images for both microscopy and photomicrography. Images are further guaranteed clarity by an N.A. 1.40 achromatic / aplanatic condenser. Added to this top microscope value is a full range of Olympus accessories — apochromatic objectives, photographic apparatus, exposure meter, phase contrast attachment, micro viewing screen, a darkfield condenser, a fluorescent light source, and more. Please write for a catalogue to your local distributor or to any of the addresses below:

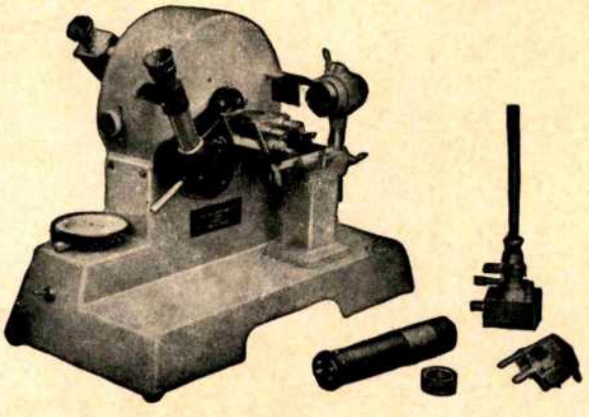
BS Precision Instruments

The Improved Type Pulfrich Refractometer

This instrument, in its modern styling, still embodies the requirements laid down by Mr. Guild of the National Physical Laboratory and the advice of research workers in various laboratories.

* CAN BE SUPPLIED WITH A DIFFERENTIAL CELL COMPLETE WITH COLLIMATOR AND SLIT FOR MEASUREMENT OF REFRACTIVE INDICES OVER THE RANGE 1·26 TO 1·95.

The interchangeable prisms, each covering a recommended range of refractive index, are of 60° refracting angle and are mounted in individual water jackets.



Please ask for Details 'N'.

We now have capacity for aluminising certain types of mirrors, at short notice.

NATURE Volume 232 JULY 16 1971

Whose Rate for the Job?

THE British Government seems well on the way to making a nonsense of its labour relations with the scientists on its payroll. In the past few weeks, even those in the scientific civil service whose inclinations lie more in scholarly research than towards the corridors of power have been offended by the parsimony with which the Civil Service Department has dealt with the most recent investigation of the Pay Research Unit into the relationship between salaries in the scientific civil service and salaries of scientists elsewhere. Briefly, the members of the scientific civil service who are above the recruitment grades in status have been awarded no pay rise in the current year (see *Nature*, **232**, 76 ; 1971). To be sure, many of those still working their way up the promotion ladders will have something extra in their pay packets, but there is little doubt that the settlement which the government has proposed, and which may well be modified by the compulsory arbitration to which it will now be subjected, represents a considerable injustice for many senior civil servants. One danger is that the bitterness evoked by this dispute will impede many of the reforms which have seemed to be in prospect in recent months as part of the painfully slow implementation of the Fulton report. More seriously, it is now possible that the government may wreck the whole basis on which it has proved possible in the past to persuade scientists to work in the public service.

What has gone wrong ? To begin with, it is a great misfortune that the government's pay offer should be based on an apparently confidential piece of research carried out by the Pay Research Unit. Why not make this public ? For objective comparisons between the salaries of civil servants, living as they do on a rigid salary structure, and scientists working in industry or commerce, are bound to be extremely hazardous. For one thing, the spread of salary in the civil service is much more closely linked with age than it is in industry. For another, no amount of arithmetic can accurately evaluate the fringe benefits which civil servants enjoy, especially holidays and pensions. After all, the importance of a lush but non-transferable pension scheme is that it persuades civil servants, especially the more senior of them, to put up with financial indignity rather than to move elsewhere.

The comparison between the civil service and industrial life is, however, most of all vitiated by the way in which promotion only rarely carries a scientist in the civil service into other kinds of activities. This was one of the complaints of the Fulton commission about the present organization of the civil service. Briefly, a man or woman who joins the scientific branch is likely to stay there until he or she retires. In other walks of life, and especially in industry, the scientific laboratories are increasingly (and rightly) regarded as stepping stones to administrative or managerial jobs. The result, of course, is that attempts to compare industry with the civil service are comparisons of quite different populations. There may be something in the view, recently put forward by the Confederation of British Industries (see *Nature*, **230**, 344 ; 1971), that the national interest would be better served if there were greater mobility between scientific research and administration, as indeed the Fulton commission has proclaimed. The fact that there are at present so few opportunities of this kind is not, however, the fault of the scientists concerned but of the government. It is entirely understandable that the scientists should feel hard done by.

However solemnly the advice of the Pay Research Unit may have been followed in the negotiations so far, the impression remains that the wellsprings of the government's meanness lie in its appraisal of future needs in the government research laboratories. With the continuing decline of defence research and with the doctrine of non-intervention as a guide, nobody will be surprised that the present British government should be more embarrassed than its predecessor by the numbers of scientists in the scientific civil service. It follows that in its pay negotiations, the government is bound to feel it has the whip hand. But is it really sensible to hope that a sufficient show of meanness will make that other problem go away by persuading young people not to work for the scientific civil service and by persuading more senior members to look elsewhere for new careers ? Such arguments are certain to be recipes for continuing trouble. If the scientific civil service does have too many people, why not work out constructive ways of making fuller use of them?

The underlying question is the extent to which the British Government intends to make constructive use of scientists and their craft. So far, after more than a year in office, the government has had hardly anything to say on the subject. Although there is a sense in which, by comparison with the all too strident utterances of Mr Anthony Wedgwood Benn and Mr Harold Wilson on the subject, silence is a virtue, yet the lack of a policy in such an important field is indefensible. Moreover, there is no prospect that the government's problems will be solved at one fell swoop when Mrs Margaret Thatcher, the minister for education and science, has had a chance to mull over Sir Frederick Dainton's report on the organization of civil science within the government, for it will still be necessary to decide on what scale the government should attempt to strengthen the competitiveness of British industry by means of publicly sponsored research and development. In passing it must be said that on what seems to be the threshold of membership of the European Economic Community, it will be absurd if the British Government chooses to eschew one of the few then permissible methods of stiffening domestic industry. In short, and whatever it may think at present, the British Government is going to need not merely the efforts of its scientists but their goodwill as well.

What Future for Euratom?

ONE of the least dazzling parts of the British Government's policy declaration last week in favour of British membership of the European Economic Community is the passage dealing with what is formally known as the European Atomic Energy Community, Euratom for short. The case for a British link with the EEC is by now so self-evident that it hardly needs to be made, yet the case for membership of Euratom is so meagre as to be non-existent. Even the more enthusiastic supporters of the European venture should acknowledge that, if only so that there shall be no great disappointment over what happens—or, more likely, does not happen—in the years ahead. For the truth is that the issue of Euratom membership is so nearly an irrelevance as to be an embarrassment. It would be in everybody's interest if the prospect of four extra members were now taken as a sign that the time has come to put Euratom on a sounder footing than in the past ten years.

The greatest disappointment has, of course, been the failure of Euratom, even when supported by the full political weight of the European Commission, to arrange for seemly collaboration in nuclear power development on a European basis. To begin with, in the late fifties, there seemed every chance that an organization such as Euratom would have useful work to do. Pre-Gaullist governments of France, urged on by a liberally minded Commissariat de l'Energie Atomique, were all for international collaboration, while the then government of Germany regarded Euratom as a means of making up for time lost during the long postwar uncertainties. In the late fifties, the pace of industrial development in Italy had begun to quicken in fields such as petrochemicals and plastics, so that there too the chance of moving ahead quickly in nuclear energy seemed entirely welcome. In the event, French hankering after nuclear independence in the military field proved to be a serious stumbling block. So too, by the mid-sixties, had become the sneaking suspicion or at least greed in the heart of every European government that there were rich pickings to be had in the design, construction and sale of nuclear reactors. In retrospect, it is just possible that these centrifugal tendencies could have been beaten off by a sufficiently imaginative and forceful organization in Brussels, but it is now even more clear than it appeared to be at the time that the first plans laid by the Euratom organization were too ambitious and too hastily prepared. Schemes like that for developing a reactor cooled by organic liquids were imaginative, it is true, but it would have been more prudent if in its early days Euratom had cut its teeth on projects more likely to be successful. More modest plans would also have been more winsome, especially for those national organizations threatened by the then prospect that Euratom might succeed in all it tried to do. But in the event, things have turned out quite differently. The research programme has for the most part failed.

To be sure, there are some redeeming features, the chief of which is the cooperative programme for research on thermonuclear fusion. Evidently it is easier for nations to collaborate with each other when their national interests appear to be less directly threatened. The investment of Euratom countries in the Dragon reactor will probably be, in the long run, a benefit, hard though it may turn out to be to quantify it. The most serious complaint against the way in which money has been spent on collaborative research in the past fifteen years is that Euratom has conspicuously failed to prevent the separate development of fast reactor projects in France, Italy, Germany and—now—the United Kingdom. As a monument to that failure, however, there remains the large research centre at Ispra (in Italy) with a staff of close on 2,000 and with no clear continuing reason for existence. In the circumstances, it is no wonder that the European Economic Community is making heavy weather of the task of working out a forward plan for Euratom. Each year since 1969, there has been talk of a long-term budget within which Euratom and its research stations could settle down to a useful job, and as a part of that process, governments, officials and industries have made what seems to be a sport of trying to suggest what kinds of work Euratom should now undertake. Some would make Ispra into a centre for environmental research. Others would turn it into a kind of international standards laboratory. But somehow the five year budget never materializes. If Mr Harold Wilson and those who oppose British membership of the EEC will allow the concept of British membership to become real, there is every chance that the negotiations now under way in Brussels within the EEC will lead to a three-year plan to tide over the period between now and the point at which Britain would be a full member of Euratom at the end of 1973.

What needs to be accomplished? The most valuable and certainly the most durable of the functions of Euratom is the safeguards system by means of which the community attempts to keep track of nuclear materials within the member countries. It is true that the safeguards system has never been quite the thing it might have been since the Government of France declared that some method must be found of excluding military explosives from the safeguards provisions of the Euratom treaty. Since then, it has never been quite clear to what extent Euratom is allowed access to French production plants on the understanding that the information gathered should not be publicized. Another possibility is that there are substantial parts of the French military explosives programme which are never included in the safeguards net. Moreover, it is not clear at present how much the Euratom safeguards will be transformed by the negotiations now under way with the International Atomic Energy Agency with a view to substituting Euratom controls for those that will in due course be administered from Vienna. The result is that nobody can safely predict how British membership of the EEC would affect the operations of British nuclear establishments. Would, for example, the fusion plants at Capenhurst now making enriched uranium for civil purposes be subjected to international inspection even though Britain is formally exempted from the provisions of the Non-Proliferation Treaty on the grounds of being or having been a nuclear power? These and many other questions like them are at present exceedingly obscure. The Euratom safeguards system, by all accounts the best feature of the community's activities, is plainly in need of making clearer and simpler if it is indefinitely to survive.

No Jobs for the Boys

A GREAT many active researchers in the United States are still able to remember and even to recall with a mixture of bravado and nostalgia how they were first compelled to find jobs in unlikely and sometimes unsuitable occupations—schoolteaching, salesmanship or shopkeeping. In part, these hard luck stories are an illustration of how deeply the depression of the thirties left its mark on all kinds of professional people then beginning their careers; when jobs are scarce, the newcomers inevitably find themselves at the back of the queue, with the result that whole cohorts of trained people may occasionally find themselves doing jobs for which they were not trained and which sometimes require no skill at all. But the way in which the tales of old heroism are remarked on is also a sign of the professionalization of science in the past few decades. It has now become less easy for men and women trained as scientists to earn their livings in other jobs. For one thing, training lasts so much longer that it counts as a valuable investment of time if not of money to new entrants to the labour market. Second, there is a real sense in which an interrupted career in professional science may be irreparably damaged.

The figures for unemployment in the United States now published by the National Science Foundation (see page 150) fit neatly into the pattern of employment prospects to be expected at times of economic recess. Among scientists as a whole, the rate of unemployment has increased—almost doubled—in a year but is still much better than that for the labour force as a whole (6.5 per cent in the first quarter of 1971). Skill is evidently an advantage still, which is borne out by the way in which people with PhD degrees had one of the lowest unemployment rates of all—1.4 per cent in the first quarter of the year compared with 3.5 per cent for less highly qualified scientists. Evidently one moral to be learned from this is that a person who has embarked on a career as a scientist will not benefit his employment prospects by refraining from completing a PhD degree.

True to the pattern of recession, the statistics also show that newly qualified people are the hardest hit, and there is nothing in the statistics to show that American employers have accepted the demands of the Women's Liberation. (In the beginning of 1971, the unemployment rate was twice as high among women scientists as among men scientists.) Predictably, many of the unemployed had been shaken out of defence and aerospace. The sobering tendency in the statistics now published is that which shows the great duration of the period of unemployment—an average of seven months by the beginning of June this year. With the next crop of graduates about to tread on the heels of those still left over from 1970, it is plain that the present recession must leave a lasting scar.

What solution can there be? No amount of vigorous action, such as that intended by the host of bills now bemusing Congress with proposals for spending money on the retraining of scientists and engineers in the gentle causes of the fight against pollution, will make up for the interruption of young people's careers and the destruction of their expectations that the present recession has caused. Unhappily, however, it helps very little to do what the Administration has done and to argue that, if there are not enough jobs to go round, the best solution is to restrict substantially the numbers of stipends available for those wishing to enter graduate schools. On the face of things, the incidence of unemployment is greatest among the age groups from 25 to 35. Only some of these, at most a third or something like 1,000, will be people with PhD degrees who have left graduate schools in the sixties. Moreover, most of these are people trained in chemistry or physics—the incidence of unemployment in other fields is much more modest. Alarming though the figures may be for the individuals concerned, they are extremely small compared with the annual production of PhDs in the United States in recent years—18,000-odd in all the sciences and engineering in the academic year now finishing. But in any case, as the figures themselves show, a PhD degree is an advantage, not a handicap, in looking for a job, at least in comparison with a lesser qualification. The case for reducing the level of support for graduate schools is, in short, entirely independent of the present employment.

NATURE

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

Cotteau's "Echinides de la Sarthe"

A NOTICE of Cotteau et Triger's *Echinides de la Sarthe* in a recent number of NATURE (June 15, p. 120) is likely to convey a false impression of the accuracy of M. Cotteau, and throws considerable doubt on the value of his work. It is not often that French scientific men are as conscientious as he is in the examination of authentic types. There is hardly a collection of fossil Echini which M. Cotteau has not examined; and his thorough acquaintance with all that has been written on his subject, as well as his intimate correspondence with the principal echinologists, is a sufficient guarantee that no important memoir (such as Wright's monograph) could have escaped him. Anyone who will take the trouble of turning to Cotteau's work (p. 111) will find, under *Pseudodiadema hemisphæricum*, a notice of Dr. Wright's figure of the same species (so much superior, with many others, to Cotteau's?) and a reference to his description. Nor is this an isolated case. Throughout the work M. Cotteau discusses and criticises more or less the results of this very monograph, said to have been overlooked by him. The mistake Cotteau is accused of making of assigning to Desor instead of Agassiz the specific name of *Pseudodiadema hemisphæricum* is entirely unfounded. Referring again to p. 111., we find, as a synonym, *Diadema hemisphæricum* Agass. M. Cotteau, like many continental and American writers, does not interpret the notation of species as is required by the laws of the British Association, but for that reason he should not be accused of committing mistakes which his own writings show him not to have committed. M. Cotteau, in common with others, looks upon nomenclature simply as a matter of registration; and when M. Desor transfers to *Pseudodiadema* the *Diadema hemisphæricum* Agass., M. Cotteau writes, therefore, *Pseudodiadema hemisphæricum* Desor, and not Agassiz; he may be wrong, according to the principles of the writer in NATURE, but he has not, either in this instance or in the other cases alluded to, committed a mistake through ignorance of the subject.

A. AGASSIZ

From Nature, 4, 220, *July* 20, 1871.

OLD WORLD

SCIENTISTS' PAY

Continuing Dispute

THE date for arbitration of the pay dispute between the members of the scientific civil service, represented by the Institution of Professional Civil Servants, and the Civil Service Department has been fixed for August 12, and, if necessary, August 13, at Church House, Westminster. The proceedings of the arbitration inquiry will not be held in public, even though the Institution of Professional Civil Servants had been hoping to arrange either that the inquiry would take place in a hall sufficiently large to accommodate some hundreds of its members, or, alternatively, that the proceedings would be relayed to a room elsewhere.

Between now and the arbitration date, the institution has also arranged a series of public meetings which are expected to provide good business for the shrunken telegraph service of the British Post Office Corporation in the shape of messages to members of parliament. With an eye to the staff of the Atomic Energy Research Establishment at Harwell, a meeting has been arranged for Friday, July 16, at the Fitzharris School, North Court Road, Abingdon (8.15 p.m.). It is hoped to arrange a meeting at Portsmouth on Monday, July 19, at the Civil Service Club and a meeting at Reading on Wednesday, July 21, at the Great Western Hotel (6.30 for 7.00 p.m.) and at the Cooperative Hall, Western Road, Weymouth, on Thursday, July 22 (7.00 for 7.30 p.m.).

The Institution of Professional Civil Servants intends to bring its campaign of publicity to a climax with a public meeting at the Central Hall, Westminster, on Tuesday, August 10.

The statistics available to the Civil Service Department do at least give the lie to the suspicion that the pay dispute has arisen at a time when the strength of the scientific civil service is declining. Since 1965–66, for example, the number of Principal Scientific Officers has increased from 1,530 to an estimated 1,748 in the current financial year. Similarly, the number of Senior Scientific Officers has increased by almost 20 per cent to a total of 1,244 and there is an even larger proportionate increase in the number of Senior Principal Scientific Officers (whose salaries are determined by a different procedure from that which has occasioned the present dispute) from 541 in 1965–66 to 668 in the current financial year. During the same period, the numbers of Senior Experimental Officers have increased even more dramatically, from 1,471 to 2,090. By comparison, the numbers of scientists in the recruitment grades have increased less quickly over the years, suggesting that the managers of the civil service have done what they can to lessen the pressure on pay by increasing the numbers of comparatively senior posts available.

MINERAL RESOURCES

Metals or Mountains?

THE announcement last week by Sir John Eden, Minister for Industry, of grants totalling up to £50 million to aid mineral exploration of non-ferrous metal ores, fluorspar and potash in Great Britain is certain to be welcomed by the mining companies and equally certain to be regarded with reserve by the conservation lobby. The minister, in announcing the scheme, in which the government will contribute up to 35 per cent of the cost of exploration and evaluation, stressed that the normal planning controls under the Town and Country Planning Acts would still apply. In spite of these reassurances, such a scheme, with full ministerial backing, is bound to increase the pressure to grant planning approval in any part of the country.

The confrontation with the conservationists arises because these minerals are found in older rocks which make up the mountains of Britain. These are also the areas where most of the National Parks are found. Before the present scheme was announced, the Rio Tinto-Zinc Corporation applied for permission to prospect within the Snowdonia National Park. The inquiry into their application was held last March and the decision of the Secretary of State for Wales is expected soon.

The announcement of the scheme comes at a time when the richer and more easily mined ore fields in other countries are being worked out. There has been no large scale mining in the UK since the end of the nineteenth century when the low quality of ore coupled with the mining expansion abroad eventually made it uneconomic to continue mining. But developments since then in mining techniques as well as the high cost of importing these minerals (£600 million a year) have made it economic to mine low quality ores.

Some lead and zinc are being produced as by-products of fluorspar mining in Derbyshire but the only non-ferrous metal currently being mined on any scale in Britain is tin in the west of England. There are, however, known to be deposits of copper, tungsten, gold, barium and uranium. The extent and quality of the known deposits are mostly unknown and the aim of the grants is to encourage mining companies to prove the mineral resources of Britain.

The government will recover the grant with accumulated interest if a successful mine results from the exploration. Sir John also pointed out that as well as the economic advantages of new mines, chiefly on the balance of payments, there would also be more jobs in parts of the country where they are most needed. Such advantages must, however, be weighed against the possible damage to the countryside if wholescale mining were allowed to take place.

Stars in Rock

by our Soviet Corresponden

ANCIENT rock carvings in Armenia (dating from 8000–1000 BC are reported to have revealed a considerable degree of astronomical knowledge in their makers. The carvings, which have been found at various sites in the Armenian highlands, indicate that the then inhabitants of the region divided the year into twelve parts, revealing a fairly good understanding of the length of the year and of the lunar month.

The most detailed astronomical carving is one in the Martuni region of the Sevkar foothills. Here the carving is exceptionally deep and a great deal of detail is preserved. It shows, on the left, the three bright stars of *Cygnus* in a line, with the sizes of the stars roughly proportional to their apparent brightness. Beside them is a pictogram of two men holding a serpent above their heads. This, says Dr B. Tumanyan, Director of the Observatory of the State University of Erevan, indicates the great antiquity of the constellation name of the Serpent-Bearer (*Ophiucus*).

In the top left hand corner of the picture, there are numerous dots and crosses representing the stars of *Delphinus* and the part of the Milky Way between *Aquila*, *Delphinus* and *Sagitta*. At the top there are pictograms of a sword, a shield and two crosses and a triangle, in the section where *Cygnus*, *Lyra* and *Vulpecula* should lie. The layout makes it quite clear that the pictograms represent the stars of this area, and thus indicate very primitive groupings and names for these stars.

According to Dr Tumanyan, detailed study of the carving suggests that it dates from c.3000 BC.

NEW WORLD

Cancer Compromise Almost Unites Senate

by our Washington Correspondent

THE tussle between Senator Edward Kennedy's Health subcommittee and the Administration over the organization of cancer research ended last week in an atmosphere of mutual back-slapping. A compromise bill in the name of the Administration went through the Senate with only one lonely voice raised in dissent, and if the bill survives the rest of the Congressional mill in its present form, hundreds of millions of dollars a year will be poured into an independently funded cancer agency based on the present National Cancer Institute. The compromise, worked out behind the scenes of the Kennedy Committee (see *Nature*, **231**, 414; 1971), seeks to set up an agency unfortunately and misleadingly called the Conquest of Cancer Agency, geographically located within the National Institutes of Health, but with a separate budget and with a director who is responsible directly to the President. A moot point, and the one on which Senator Gaylord Nelson of Wisconsin based his opposition to the bill, is whether the agency will in practice operate within the NIH, or whether the administrative arrangements that have been worked out for it will take it essentially outside the confines of the other nine institutes which together make up the NIH.

But one of the more disturbing aspects of last week's debate—if a seventy-nine to one split can be termed a debate—is that the Conquest of Cancer Agency has been sold to the Senate and the public as a measure which has a good chance of leading in the near future to a cure for cancer. The suggestion is that a massive infusion of capital into a NASA-style agency charged with the task of finding a cure for cancer is all that is needed to come up with an answer to the cancer problem. That was certainly the impression unashamedly put out by Senator Jacob Javits of New York, a member of the Kennedy committee and a co-sponsor of the bill, when he told his fellow Senators that "Senators Dominick, Kennedy and I, and a majority on the committee, feel that we are so close to breakthroughs in cancer; that cancer represents to the people such an awesome disease or illness, that we must, as a national effort, quite apart from the scientific question, undertake a crash programme under a unified direction, to make the final breakthroughs. . . . The country finds the death rate from cancer unacceptable because it thinks it is imminently avoidable. That is the question we think we are close enough to breakthroughs on, and that one final drive will do it."

There is a real fear in the biomedical community that if the cancer cure agency is sold to the public in these terms, and fails to come up immediately with the answers, scientists and science alike will be discredited. The fact that a so-called cure for cancer is probably not as attainable as the Moon could come as a rude shock to those who will be looking for the proposed agency to produce the right answers at the mere wave of the financial wand. These sentiments were eloquently expressed only last month by Albert Sabin, founder of the oral polio vaccine, who has been widely tipped to head the new cancer agency. Speaking at a meeting in Brussels, Sabin said that researchers working on such targeted research are worried because they have been charged with a task which to the public seems to be a question merely of finance, but which in practice is much more complicated.

Those sentiments apart, the passage through the Senate last week of the Administration's bill is an object lesson in Congressional politics. The tussle between President Nixon and Democratic Congressmen led by Kennedy has already been well documented in *Nature*, but which side has in practice won the battle will probably not become clear until the proposed agency has been working for some time. At the root of the disagreement is whether or not the Conquest of Cancer Agency will remain in practice as well as in theory a part of the National Institutes of Health. Kennedy originally sponsored a bill in the Senate (numbered S34) which proposed in essence that the National Cancer Institute should be taken outside the National Institutes of Health and raised to the status of an independently-funded agency reporting directly to the President. But the Administration later introduced a bill (numbered S1828) which proposed instead that the National Cancer Institute should remain as a bureau within the NIH, and that it should have a separate budget. The bill which was passed by the Senate last week was something of a compromise between these two positions, although it retained the number S1828, meaning that it was the Administration's bill.

Kennedy's proposals met with the almost unanimous disapproval of the scientific community, whose witnesses before the Health subcommittee deplored the suggestion that the proposed cancer agency should be taken out of the NIH and away from other biomedical research. And it is on this point that Kennedy has been seen to come into line with the Administration's thinking, for the bill which went through the Senate called for the setting up of the Conquest of Cancer Agency within the NIH, but with a director reporting to the President. The bill in particular lays down some specific guidelines for cooperation between the Conquest of Cancer Agency and the NIH. The most important is that the director of the agency is authorized to "take necessary action together with the Director of the National Institutes of Health so that all channels for the dissemination and cross fertilization of scientific knowledge and information existing prior to the effective date of this Act between the National Cancer Institute and the other Institutes of Health shall be maintained between the Agency and the Institutes of Health to ensure free communications between cancer and other scientific, medical and biomedical disciplines".

But these provisions do not satisfy Senator Nelson, who argued and voted against the bill, and Senator Cranston from California, who expressed doubts but voted for the bill. Nelson made it clear that he believes that it is the Administration which has sold out to the original Kennedy proposal rather than the reverse. Referring throughout his remarks to the proposed agency as an institution separate from the NIH, Nelson warned that other institutes within NIH will want similar treatment, as in fact the National Heart and Lung Institute has already requested, and this bill, if it emerges unchanged by the House, will signal the break-up of the NIH itself. "I have repeatedly asked the proponents of this measure—that is, the proponents of creating an independent institute outside of NIH—just what is to be gained by it . . . there is not much of a reason for it except a kind of emotional commitment to do something with an independent institute that they think cannot be done if they remain within the NIH, the finest institution of its kind on Earth," Nelson said.

Another important plank in Nelson's platform is that under the terms of the bill, the Director of the NIH will be responsible for about $100 million worth of cancer-related research within the nine remaining institutes of health, while a further $332 million will be spent by the proposed Conquest of Cancer Agency housed within the NIH but reporting directly to the President. "It does not make much sense at all," he said. "I think that if everybody sat down and thought about it for a while, they would recognize that this is not the best approach to accomplish the end we all seek." Cranston echoed these sentiments, believing that the suggestion for cooperation between the director of the proposed agency and the Director of the NIH is insufficient. "What is needed is statutory authority making clear that the Director of NIH should have the formal responsibility of submitting the cancer programme and budget to the President, along with his evaluation of the cancer programme and appropriate recommendations," he said.

In the event, however, the bill went through with only Nelson recording his dissent, and the nature of the compromise worked out between the supporters of Kennedy's original bill and those who acceded to the Administration's original proposals can be evinced from an extraordinary tale told by Javits. "Many people always think that we are very strong minded and that we want to have our *imprimatur* on everything and will never yield a single prerogative or permit the name of anyone else to get on a bill except our own names, but in this instance we had finally to prevail on the Senator from Colorado (Dominick), who felt he wanted the Senator from Massachusetts (Kennedy) to bring the bill to the floor."

UNEMPLOYMENT

Grim Prospects

by our Washington Correspondent

THIS year's crop of science and engineering graduates who have already found themselves swelling the ranks of the unemployed do not need to be reminded that they have been thrown on to the job market at its most depressed time since the Second World War. The full extent of unemployment at present remains, however, a subject for speculation, but some alarming indications can be gleaned from a survey conducted in May by the National Science Foundation, the results of which have now been made public.

Table 1 Number and Rates of Unemployed Scientists, by Field of Science, 1971

Field of science	Responding	Not employed and not seeking employment*	In labour force	Unemployed	Unemployed rate (%)
Total	253,078	8,003	245,075	6,337	2.6
Chemistry	73,008	2,576	70,432	2,101	3.0
Earth and marine science	18,724	535	18,189	486	2.7
Atmospheric and space science	5,243	198	5,045	142	2.8
Physics	30,220	1,089	29,131	1,126	3.9
Mathematics	19,745	642	19,103	491	2.6
Computer sciences	8,840	223	8,617	309	3.6
Agricultural sciences	12,708	247	12,461	110	0.9
Biological sciences	39,871	855	39,016	656	1.7
Psychology	20,319	731	19,588	304	1.6
Statistics	2,465	92	2,373	51	2.2
Economics	9,767	318	9,449	154	1.6
Sociology	5,512	251	5,261	196	3.8
Political science	4,286	134	4,152	141	3.4
Anthropology	1,029	48	981	13	1.3
Linguistics	1,341	64	1,277	57	4.5

* Includes such groups as retired, students, housewives, and others not in labour force.
Source: National Science Foundation, National Register of Scientific and Technical Personnel.

Based on returns to a questionnaire sent out to 300,000 scientists, the NSF's conclusion is that 2.6 per cent of all qualified scientists were out of work in the spring of 1971. Compared with a national average unemployment rate of 6.5 per cent during that period, these findings may not evoke too much sympathy on the dole queues. But the important point is that they correspond to the period immediately before this year's new graduates came off the university production line, and with the abundant reports of cutbacks by industry in graduate recruitment, they are cold comfort for new graduates seeking employment. The estimates should also be considered as minima, for they are based on replies from scientists who could be reached, and they do not take account of the fact that many scientists were underemployed or had left science for other sectors of employment.

Chief among the findings are:

- 1.4 per cent of all doctorates were out of work this spring, compared with 0.9 per cent last year, while the unemployment rate among nondoctorate scientists was 3.5 per cent compared with 2.9 per cent in 1970.
- Young scientists were the hardest hit, with an unemployment rate of 5.3 per cent.
- The unemployment rate among women was running at 5.2 per cent, compared with 2.3 per cent for men.
- About 45 per cent of unemployed scientists said that their last science-related employment was supported to some extent from government funds.
- Scientists who are not citizens of the United States reported an unemployment rate of 4.2 per cent, compared with 2.5 per cent for US citizens.

Chemists and physicists between them accounted for half the total of unemployed scientists in the survey, and unemployment rates in these two sectors were running at 3.0 and 3.9 per cent respectively, compared with 1.5 and 2.3 per cent in 1970. Sociologists, political scientists and computer scientists also reported unemployment rates greater than 3 per cent (see Table 1). It also seems that unemployed scientists who were previously employed by industry have been most affected by the present job shortages, for in 1970 industry and business employed 31 per cent of the scientists in the national register, but 38 per cent of the unemployed scientists in the NSF survey gave industry and business as their previous employers.

The hardest hit area is California, where 42 per cent of the unemployed scientists were located, and in Seattle, Washington, the unemployment rate among scientists was running at 5.6 per cent in the spring. The Department of Labor has in fact designated 14 areas as being severely affected by unemployment of scientists, engineers and technicians, and the chief factor linking many of the areas is a high concentration of defence and aerospace activities. The areas include Orange County, California, Seattle, Dallas, Long Beach, California, Atlanta and Cape Kennedy.

Short Notes

THE Kitt Peak National Observatory has a new director in the person of Dr Leo Goldberg, director of the Harvard College Observatory. Dr Goldberg will succeed Dr Nicholas U. Mayall on September 1. Dr Goldberg, who is an astrophysicist specializing in atmospheric problems, has divided his career between Harvard and the University of Michigan.

NEWS AND VIEWS

Circular Polarization and Astronomy

THE possibility that circular polarization measurements can provide significant new information about the planets has now been taken a step further. On page 165 of this issue of *Nature*, Kemp and his colleagues, who have been working at the Mauna Kea Observatory, Hawaii, report further measurements of the circular polarization in the light reflected from Jupiter, and the first measurements of circularly polarized light from Mars, Venus, Mercury and the Moon. To begin with, their new study verifies the explanation of the circular polarization from Jupiter that was put forward tentatively when the discovery was announced two months ago (*Nature*, **231**, 169 and 170; 1971). It also seems probable that the circular polarization recorded from the other planets can be explained by the Jupiter mechanism, or a modification of it. But with positive measurements from several planets now under their belts, Kemp and his colleagues allow themselves a little more speculation about the applications of their discoveries to studies of the planets than they did two months ago.

In the case of Mars and the Moon, the occurrence of circular polarization in the scattered light appears to be attributable to their dust-covered surfaces, so that the measurements are unlikely to provide any information that is not already known. The same explanation probably holds for the single observation of circular polarization from Mercury that Kemp and colleagues report, although in this case any information gathered is likely to be more valuable. It remains to be seen whether the well known awkwardnesses that arise in observing a planet so near the Sun will prove to be serious obstacles.

The data from Jupiter and Venus, and the possibility of obtaining data from Uranus and Neptune, are likely to be more important, however. In the case of Jupiter and Venus, the origin of the circular polarization has to do with their dense atmospheres (as is also the case for measurements of Mars at blue wavelengths where the effect of the thin Martian atmosphere seems to become significant). The mechanism that Kemp and colleagues put forward two months ago for the origin of the circular polarization from Jupiter has now been essentially verified by the way in which the circular polarization from the northern and southern hemispheres of the planet altered through the period of opposition (opposition was on May 23). The way is now open, then, for a detailed examination of the variation in circular polarization across the surface of Jupiter when the equipment for examining small areas of planet is available. Already, however, there is interest in the possibility of significant variation in the magnitude of the circular polarization from the vicinity of the Red Spot. The Red Spot is in the southern hemisphere of Jupiter, and Kemp and colleagues report unusual behaviour of the circular polarization averaged over the entire southern hemisphere with which the Red Spot may conceivably be related. Kemp and colleagues have already reported evidence that the leading edge of the Red Spot is more strongly circularly polarized than the trailing edge (*Nature*, **231**, 169; 1971).

The outlook then is promising that circular polarization measurements, particularly of the outer planets, will provide work for some time to come. Historically this prospect is an extension of research that has been carried out by Kemp and others for the past year or two on circular polarization in the light from white dwarf stars. On the face of it, the detection of circular polarization from white dwarfs is at present likely to be of more significance than the planetary work, largely because the virtually featureless spectra of many white dwarfs are a bar to a better understanding of their nature. Through the work of Kemp and others, however (see *Nature Physical Science*, **231**, 21; 1971), it is now clear that the circular polarization that has now been observed in the light of three white dwarfs—Grw + 70° 8247, G195-19, and G99-37—can be related to the strengths of their magnetic fields. The measurements indicate fields of the order of 10^6–10^7 Gauss. This work is important, if only because it lends support to an essential requirement of all pulsar theories—that the rapidly spinning neutron stars which are believed to be the origin of the pulsating signals have the enormous magnetic fields of the order of 10^{12} Gauss that are necessary for an understanding of their electromagnetic emission. Neutron stars are expected to have diameters of the order of 10 km, compared with 1,000 km for typical white dwarfs, so bearing in mind that the magnetic field increases as the inverse square of the radius as a star collapses (assuming the conservation of magnetic flux), there is now encouraging observational support for the view that the collapse of a main sequence star to a neutron star can lead to the required large fields of 10^{12} Gauss.

The circular polarization from white dwarf stars has its origin in the characteristics of blurred spectral lines in a strong magnetic field. To be sure, Jupiter is in many ways surprisingly close to being a white dwarf, but it was clear from the start that the mechanism which accounts for the white dwarf measurements could not explain those from the planets. For one thing, a field of at least 10^3 Gauss would be needed, rather than the 10–100 Gauss which seems to be indicated for Jupiter. So there are several different mechanisms in the air for the origin of the circular polarization, depending on the observed object, with much work still to be done on each of them. In the current *Astrophysical Journal*, for example, Shipman of the Hale Observatories examines Kemp's theory for the white dwarf Grw + 70° 8247, and is able to modify it to explain better the wavelength dependence of the circular polarization measurements (**167**, 165; 1971). Where Kemp predicted that the circular polarization would increase linearly with wavelength, Shipman is able to reproduce, very roughly, the peak in the fractional polarization that is observed for this star at 4000 Å by a re-examination of the conditions in the star's atmosphere. The anomalously large circular polarization that has been reported in the infrared remains a problem, however. Clearly there is much work to be done, both by theoreticians, and at the telescope, to see how general is the form of the spectral dependence observed for Grw + 70° 8247. Together with the interesting data that may come out of the planetary measurements, the circular polarization measurements are a rich seam which will be worked for many years to come.

NUCLEAR FUSION

Tokamak Excels

from a Correspondent

The conference on plasma physics and controlled fusion research organized by the International Atomic Energy Agency at Madison, Wisconsin, from June 17 to 23 was the fourth in the series of meetings which are held at three-year intervals. They constitute the forum for the international exchange of information on progress towards an ultimate power-generating fusion reactor. At present the principal concern is the plasma confinement problem, and in spite of the title the only plasma physics covered was that held to be directly relevant to fusion.

Many different schemes for plasma confinement are under study and a good deal of attention is given at these international meetings to their relative progress and future promise. This latest meeting was fairly unremarkable in the sense that no outstanding new results or concepts were presented; the remarkable feature was that for two successive meetings in the series the Russian Tokamak system has maintained a lead both in performance and promise over rival schemes.

Thus Dr E. Meservey (Princeton University) presented results from the Princeton Tokamak which in broad terms confirmed those obtained earlier by Russian workers on their T-3 machine in Moscow. There are some differences and attention was naturally concentrated on these. For example, the electron temperature is strongly peaked near the axis in the American machine, whereas in the Russian one the profile is relatively flat. There are other differences which seem to be attributable to differences in interpretation of essentially the same experimental data. Thus the Russians think that the containment time for particles greatly exceeds that for the energy whereas the American view is that they are about equal.

Dr V. S. Strelkov (Kurchatov Institute, Moscow) presented results from the latest Russian Tokamak, T-4. This has a higher magnetic field (50 kG) and the stabilizing copper shell is nearer to the plasma than in T-3. The plasma current has thus been increased by almost a factor of two: the ion temperature as deduced from the neutron yield reaches 650 eV. With a current of 110 kA the electron temperature is ~2 keV, the plasma density is 3×10^{13} cm^{-3} and the containment time is 10 milliseconds. These are impressive numbers but they fall short by about one order in both temperature and density and two orders in containment time over the requirements for a fusion reactor. It should be emphasized that although many features of the Tokamak discharge are not understood there are fairly clear, if expensive, lines along which the next experiments should proceed.

Whether some tortoise will eventually overtake the Tokamak hare is an interesting question. The stellarator which is closely related to the Tokamak, but much more expensive and difficult to build, seems to be undergoing a random walk rather than progress. Dr P. Reynolds (UKAEA, Culham Laboratory) presented results from his small stellarator which agree very well with the theory of classical containment. By contrast Dr K. Myamoto (Nagoya University) finds fluctuations and anomalous losses in his very similar machine. For the largest stellarator at present operating in the world, the Uragan machine at Kharkov, Dr K. N. Stepanov reported electron temperatures up to 400 eV, density ~5×10^{12} cm^{-3} and containment time ~300 µs.

Research on high beta toroidal confinement is still in an early stage as groups previously working on linear theta pinches move into the field. Typical results on screw pinches reported from Jutphaas, Culham and Garching were electron density ~10^{16} cm^{-3}, plasma temperature ~100 eV and containment time ~10 µs. This configuration relies for its equilibrium on toroidal current flow in the outer low density region. The rapid decay of this current is believed to be the limiting factor and Dr P. C. T. van der Laan (Institute for Plasma Physics, Jutphaas) discussed a variety of possible explanations without reaching any definite conclusion. Dr H. A. B. Bodin (UKAEA, Culham Laboratory) presented results on the diffuse pinch configuration which were encouraging in the sense that the configuration could be set up and its stability agreed roughly with theory but discouraging in that the temperature was limited by impurity radiation to ~10 eV. Results from a segment of the Scyllac torus reported by Dr F. L. Ribe (Los Alamos Scientific Laboratory) showed control of the toroidal drift by the addition of $l=0$ and $l=1$ fields.

In mirror research the chief result was that reported by Dr F. H. Coensgen (Lawrence Radiation Laboratory, Livermore) who finds that plasma is lost from his 2X machine at about ten times the classical rate. This fast loss is accom-

---

Mixed RNAs in Transformed Cells

In *Nature New Biology* next Wednesday, Wall and Darnell report a series of elegant DNA.RNA hybridization experiments which establish once and for all that sequences of SV40 RNA occur in large molecules covalently linked to sequences of host cell RNA in the nuclei of mouse cells transformed by SV40.

In 1968 Sambrook and his colleagues showed that, in stably transformed cells, SV40 DNA molecules are integrated into DNA molecules of the host genome. Since then, although the number of integrated SV40 genomes in transformed cells has remained a matter of dispute, numerous groups have found that SV40 RNA is present in both the nucleus and cytoplasm of transformed cells. Further, it is generally agreed that SV40 RNA occurs in the nucleus in molecules which are longer than a single complete SV40 genome and in the cytoplasm the SV40 RNAs associated with polysomes are no longer than a single SV40 genome. There is every reason to believe that these polysomal SV40 RNAs are derived by cleavage from the large nuclear RNA molecules which contain SV40 sequences, but how do these large nuclear RNAs themselves arise?

There are two obvious possibilities which have been canvassed. If several SV40 genomes are integrated in tandem in each transformed cell they might be transcribed as a single unit to yield RNA molecules longer than a single SV40 genome and containing nothing but SV40 sequences. Alternatively, the SV40 genomes may be integrated singly in such a way that they are always transcribed together with some of the adjacent host DNA; in which case the size of these RNAs would depend on how much of the host genome is transcribed and they should contain host sequences either at the 5′ or 3′ or both sides of the SV40 sequences.

To decide this issue, Wall and Darnell first hybridized to SV40 DNA RNAs from the nucleus and cytoplasm of transformed and untransformed cells. They then recovered the hybridizing RNA from the hybrids, which must contain SV40 sequences, and tested to see if it would also hybridize with cellular DNA from untransformed cells. They detected nuclear RNA molecules from transformed cells which hybridized with both SV40 and cellular DNAs. Wall and Darnell conclude therefore that in transferred cells at least some SV40 DNA molecules are transcribed together with some host DNA to give large and mixed RNA molecules. And although their results do not prove the idea that these mixed molecules are precursors of the small SV40 RNAs associated with polysomes they do not contradict it. By further refining the hybridization techniques and ultimately by fingerprinting these various RNAs it should be possible to decide if they are related as precursors and products and to learn something of the mechanisms which control transcription and messenger RNA maturation in eukaryotes.

panied by evidence of instabilities with frequencies near the ion cyclotron frequency. Because a mirror reactor requires near-classical confinement this result is not encouraging; it is possible, however, that the necessary quiescence can be achieved by careful machine design and control of the particle velocity distribution.

Theoretical work presented at the conference dealt chiefly with plasma confinement and stability in the Tokamak. There is now a fair measure of agreement on the classical theory of confinement in symmetric low beta systems. Attention is now paid to the effect of residual fluctuations on such systems and contributions from Dr S. Yoshikawa (Princeton University) and Drs A. A. Galeev and R. Z. Sagdeev (Kurchatov Institute, Moscow) reached similar conclusions by rather different routes. This work emphasizes the role of the poloidal magnetic field in plasma confinement, the much stronger toroidal field performing only an auxiliary function. On the question of stability, the situation is not clear; a contribution by Drs D. Pfirsch and H. Tasso (Institute for Plasma Physics, Garching) which showed the Tokamak to be unstable against a simple mode will undoubtedly be the subject of much critical attention.

For the first time at these meetings a session was devoted to reactor systems. The broad conclusion from this session was that within the necessarily very wide margins of error, fusion as a power source might be competitive with other systems and might offer substantial environmental advantages.

RNA

Messenger's Burden

from our Molecular Biology Correspondent

ONE of the strangest molecules that explorers of the eukaryotic nucleus have brought to light is polyadenylic acid, in almost monodisperse form. This observation became more than a mere unexplained curiosity when Lim and Canellakis reported last year that haemoglobin messenger RNA contains a long tract of poly A, which apparently largely accounts for the discrepancy between its observed and expected molecular weight.

The question of how general this phenomenon may be has now been taken up in several laboratories, and a clutch of three articles on the subject is to be found in the current issue of the *Proceedings of the US National Academy of Sciences.*

Lee, Mendecki and Brawerman (**68**, 1331; 1971) have examined the messenger RNA of ascites cells. They find that at *p*H 9, though not under more nearly neutral conditions, a large proportion of the rapidly labelling RNA fraction of polysomes is specifically trapped on a membrane filter. The fraction so obtained leaves after digestion with pancreatic or T_1 ribonuclease a sedimentable core consisting largely or wholly of adenylic acid residues, a label in adenosine being almost completely recovered in this resistant fragment, whereas a label in uridine vanishes. Moreover, the behaviour of synthetic poly A on the membrane filters makes it clear that it is the poly A segment that causes the messenger to be retained. The poly A core recovered from the messenger sediments at about the same rate as tRNA. Another property of the messenger, conferred on it by its poly A, is its tendency, depending on the salt conditions, to enter the wrong phase during phenol extraction.

Very similar results were obtained by Edmonds, Vaughan and Nakazato (*ibid.*, 1336) for the messenger RNA of HeLa cells. The poly A core was shown by polyacrylamide gel electrophoresis to have a very narrow molecular weight distribution, and an estimated length of 150–200 nucleotides. This is in fact rather too high to be accounted for by the estimated poly A content of the messenger, but it does not necessarily follow that some of the messenger is devoid of poly A: a number of other explanations are possible, for example that some of the label goes into other kinds of RNA than messenger.

The chief object of the article, however, is to treat the poly A as an identifying feature, and to look for its presence in the rapidly labelling polydisperse high molecular weight RNA present in the nucleus, which many workers in the field would like to believe is a messenger precursor. Poly A is indeed recovered from this material by digestion, and is of the same size as that found in the messenger. It makes up only some 0.5 per cent of the total. That the poly A is a part of a large RNA molecule was demonstrated by its failure to dissociate and redistribute itself between labelled and unlabelled nuclear RNA after addition of a high concentration of an organic

Acceleration of Cosmic Rays

THE drawback of the venerable Fermi mechanism for the generation of the cosmic ray spectrum is the large energies that the particles need to have before the mechanism comes into play. Although the scattering of cosmic ray particles by irregularities in the magnetic fields of interstellar space will produce an energy distribution which matches the experimental data on cosmic rays, as Fermi suggested the particles have to have initial energies of 200 MeV if they are protons, and higher energies if they are heavier particles.

A process which will raise the energies of particles from thermal energies to sufficiently high energies for injection into the Fermi mechanism is suggested in next Monday's number of *Nature Physical Science.* A group at the University of Bologna argue that particles able to take part in the Fermi mechanism may come from the nucleus of the galaxy, where they have been accelerated from thermal energies by interactions with the magnetic fields of neutron stars.

This notion seems to be inspired by the pulses recorded by Weber's gravitational wave equipment, and whatever the explanation of the data published by Weber, his results have stimulated theoretical work on the conditions in the nuclei of galaxies. Interactions among clusters of collapsed objects at the centre of the galaxy might be a source of gravitational waves, but there are other more prosaic reasons for supposing that the nuclei of galaxies contains dense matter. In any case, the Bologna group consider a cluster of neutron stars, a proportion of which have strong magnetic fields, and show how charged particles can gain energy by being scattered by the fields.

Protons need to be scattered only twice to gain the 200 MeV that is the entry ticket for the Fermi process. Heavier particles may need to be scattered more than twice, but there is no reason why the 1 BeV, 20 BeV, and 300 BeV that are the required injection energies for alpha particles, oxygen, and iron respectively should not be achieved in this way.

Little more can be said without knowing more about the abundances of the elements in the interstellar gas in the galactic nucleus, and little light is likely to be thrown on this aspect of the problem for many years. The hope is, of course, that the abundances, together with the fact that it becomes progressively more difficult to provide the heavier elements with the necessary injection energy, will provide a match with the element abundances observed from measurements on cosmic rays.

The Bologna article is well in tune with recent trends in astrophysics. The beginnings of a realization of the parts played by high energy processes and by collapsed objects are suggesting several ways in which the acceleration of cosmic rays may be accomplished. For example, particles thrown out of the atmospheres of pulsars by their rapid rotation rates may also have high enough energies to take part in cosmic ray processes.

solvent which causes the breakdown of base pairing. When RNA synthesis is stopped by actinomycin D, the poly A is also largely suppressed. Evidently therefore the poly A is transcribed from the DNA as part of the RNA chain, and is not added afterwards.

These results then provide support for the messenger precursor hypothesis, and agree with yet another study with a similar aim by Darnell, Wall and Tushinski (*ibid*., 1321). Working with HeLa cells they too find poly A in the messenger, and in small quantity in the nuclear RNA. They have also hybridized both species of RNA with the endogenous DNA under conditions that lead to the detection only of molecules with sequences multiply "reiterated" in the DNA. The hybridized RNA is then isolated by digesting away the unbound part with ribonuclease. The hybridized messenger is enriched in A, compared with total messenger. It seems then the poly A is a part of, or at least adjacent to, the rapidly hybridizing RNA sequence, otherwise it would be liberated during the nuclease step.

The function of the poly A tract in the messeger is a matter of conjecture. Because the messengers are monocistronic and the poly A is not translated, it is likely that it occupies one end of the RNA chain. From the length of the haemoglobin message and that of the poly A tract, it seems clear that there is no room for the elaborate "leader" sequences that are found in viral RNA messengers, and are of uncertain function. The poly A may be required for translation, or for attachment to the messenger, involving perhaps the group of proteins that appear always to be attached to the messenger, without evidently getting in the way of the translation machinery. This RNA–protein package, in fact, seems to be the form in which the messenger is expelled from the nucleus, and the possibility that the function of the poly A relates to the transport of the messenger into the cytoplasm may also be entertained.

BACTERIOPHAGES

Pathway to a Phage

from our Cell Biology Correspondent

ANYBODY who has looked at high resolution electron micrographs of bacteriophage T4 particles and marvelled at their intricate architecture can readily understand why more than one molecular biologist has been content to devote years fathoming out the genes involved and the steps in their morphogenesis. And the story they have to tell is becoming as fascinating as the T4 phage is intricate. The tally of genes required for T4 morphogenesis has now reached 46, no less, and that is a minimal estimate. In the current issue of the *Journal of Molecular Biology* (**58**, 685 and 693; 1971) two groups, Meezan and Wood at CalTech and King at the MRC Laboratory at Cambridge, describe in detail the functions of just four (genes 48, 54, 19 and 3) of the twenty-one genes involved in the assembly of the phage tail.

Both groups find that in *Escherichia coli* infected with strains of T4 carrying amber mutations in any one of genes 48, 54 or 19 phage baseplates—hexagonal structures with six projecting spikes which in the mature phages are attached to the tail core and its surrounding sheath—accumulate, but complete tails do not form. Because extracts of cells infected with one or other of these mutants complement and yield some infectious phage the proteins specified by these genes are able to catalyse tail formation *in vitro*. Moreover such complementation experiments indicate that the products of these three genes are required in a unique order (gene 48 product first, followed by gene 54 product and finally gene 19 product) for the polymerization of the tail core on the baseplate. Exploiting temperature sensitive mutants, King has also shown that gene 19 specifies the major structural protein of the tail core and the proteins specified by genes 48 and 54, not themselves part of the core, somehow act on the baseplates rendering them a suitable substrate for the polymerization of the gene 19 structural protein.

King has also determined the role of another gene, 3; its product is not involved in the polymerization of the tail core, neither is it the structural protein of the surrounding tail sheath (that is specified by gene 18) but the gene 3 product does react with the terminal annuli of the tail core in the absence of the sheath. It seems that the gene 3 product acts on the free end of the core and converts it to a substrate for the attachment and stabilization of the sheath protein. And once these four genes have acted in the correct order and the baseplate, core and sheath have assembled, the product of yet another gene, 15, can form the actual joint linking the sheath to the tip of the core.

As King takes pains to point out, the assembly of the tail of T4 depends on a sequence of interactions between particular gene products and a macromolecular precursor structure; apparently the various structural proteins, unable to interact strongly when in solution, strongly interact with the macromolecular substrate produced by the preceding step in the morphogenetic pathway. The gene 15 protein, for example, which joins the terminal subunits of the tail core and sheath does not react in solution with the proteins specified by genes 18, 3 and 19, but strongly interacts with them once they are assembled into a sheath and core attached to the baseplate. Presumably during assembly these proteins undergo either allosteric or chemical changes which make them suitable substrates for, and able to interact with, the next protein to be polymerized. Such a highly regulated pathway, which may well be the evolutionary consequence of the fact that the phage is assembled at sites distant from those where the

Sequence and Synthesis of Substance P

IT has been known for forty years that a substance, identified only recently as a peptide, and present in a variety of tissues, possesses hypotensive and a variety of other physiological activities. Appreciable amounts of this material are hard to come by, but in view of its broad neural activity, which is quite different from those of the hypothalamic peptide hormones, the determination of its structure is of considerable interest. The complete sequence is reported by Chang, Leeman and Niall in next Wednesday's *Nature New Biology*. The sequence is arg-pro-lys-pro-gln-gln-phe-phe-gly-leu - met - NH_2. Preparations derived from three different bovine tissues were found to have the same sequence. Substance P is inferred to occur throughout the central nervous system.

The sequence is also compared with those of two other peptides of similar activity, one, physalaemin, from the skin of an amphibian, the others eledoisin, from the salivary glands of a cephalopod. These also have eleven residues, of which four, including the last three at the N-terminus, are identical in all three molecules. In most other positions there are conservative substitutions. Physalaemin and eledoisin have pyrrolidone carboxylic acid as the C-terminal residue.

In a second article Tregear *et al.* describe the synthesis of substance P by the solid-phase Merrifield method. The product is active in respect of the various functions associated with natural substance P. This work provides a good example of the value of modern peptide synthesis technique, for it makes available in relatively large quantity a biological material, which can otherwise only be isolated in very small amounts. The authors point out the possibilities now open for its biological characterization. The synthetic material will be used to prepare antibodies, with the aid of which it should be possible to locate and assay it in nervous tissue and elsewhere.

structural proteins are synthesized, has obvious selective advantages. Phage heads, for example, cannot attach to tails unless they are complete; heads cannot therefore be wasted in incomplete and uninfectious particles. Likewise sheath protein cannot polymerize on baseplates until the baseplates have initiated the polymerization of a tail core. With every successive step rigorously dependent on all its predecessors the phage assembly line is optimized for the production of complete and infectious progeny.

CONTINENTAL DRIFT

Ice and Gondwanaland

from our Geomagnetism Correspondent

Gough's recent novel suggestion (*J. Geophys. Res.*, **75**, 4475; 1970) that the Carboniferous ice cap may have been the agent which initiated the break-up of Gondwanaland is now severely criticized by Meyerhoff and Teichert (*J. Geophys. Res.*, **76**, 4038; 1971), who rather unexpectedly take the view not that the ice cap was incapable of doing any such thing but that the idea of a large continuous Carboniferous ice sheet is not valid in the first place.

The gist of Gough's original contention was that the stresses produced by a large ice sheet could have fractured the lithosphere and initiated separation of the fragments and could then have caused the flow in the asthenosphere which allowed continental drift to continue. At the same time, the asthenospheric material would have risen in the crustal fractures to form the embryonic ocean floors. To support this idea Gough performed a simple first-order calculation for the stresses produced by an ice sheet 2 km thick having a diameter of 3,000 km and so showed that the stress differences at the surface under the edges of such a load are up to 100 bars, that the largest stress difference under the centre of the load is about 130 bars and occurs at a depth of about two-thirds of the load diameter, and that at the depth of the asthenosphere the stress would be in the range 60–90 bars, far greater than the 10 bars sufficient to produce creep in the mantle.

One of the earlier and most influential authorities for the existence of a large Carboniferous ice sheet was du Toit (*Our Wandering Continents*, Oliver and Boyd, 1937) whose detailed reconstruction showed a slightly curved ice cap 11,000 km long and 4,500 km wide covering a quarter of South America, slightly less than half of Africa, most of Australia and the whole of Madagascar, India and Antarctica. Such a reconstruction has since been accepted by most palaeomagnetists. But Meyerhoff and Teichert no longer believe it. It is their unequivocal view that "at no time during the Carboniferous and Permian did a large ice sheet occupy any part of the southern continents—with the single possible exception of Antarctica". Instead they point out that there is evidence for about thirty separate, unconnected Carboniferous and Permian ice "centres" in the southern hemisphere of which the largest, in Brazil and southern Africa, had maximum diameters of 1,600 km. Furthermore, there were apparently six in India and Pakistan and four in the Urals and north-central Siberia. The evidence for the lack of connexion between these ice centres is, according to Meyerhoff and Teichert, that all but three were mountain ice caps with radial U-shaped valleys and that even the remaining three were surrounded by highlands. Moreover, they quote numerous references which suggest that many of the known Carboniferous and Permian ice caps were not precisely contemporaneous. In short, "the concept of a single, vast, continental ice sheet over a large part of Gondwanaland has been thoroughly disproved".

The second class of objection put forward by Meyerhoff and Teichert raises issues of a rather different kind. Thus when their isolated ice centres are plotted on a reconstruction of Gondwanaland they find that many lie in the

Role of Cytotoxic Cells *in vivo*

One of the more interesting developments in cellular immunology in recent years has been the recognition of several sorts of cytotoxic cells. In almost all instances the aggressive activities of such cells have been demonstrated *in vitro*; direct observation has shown that certain kinds of killer cells will seek out and eventually destroy the hapless target cells. Work on these cell populations is now advancing towards a definition of the mechanism by which cell death is brought about and towards delineation of the role of cytotoxic cells in situations *in vivo*. Three articles in the forthcoming issue of *Nature New Biology* relate to this subject.

Alexander and Evans describe how they have brought macrophage populations in contact with either endotoxin or twin stranded RNA. Subsequently, the macrophages proved capable of killing a lymphoma cell population. This intriguing phenomenon is apparently non-specific, but it does require fairly long contact between the lymphoma cells and the endotoxin or ds RNA treated macrophages. The results cannot be explained, according to the authors, by any direct cytotoxic effect of endotoxin or ds RNA on the lymphoma cells, but it could be that a cytotoxin is released from the activated macrophages.

Peter and Dawkins quite specifically invoke a cytotoxin to explain their results. Human adenoidal cells were placed in culture with PHA and the resulting supernatants were found to be cytotoxic for mouse L cells in a manner which was superficially similar to that of a known cytotoxic antibody. The cell array present in these cultures is, of course, less well defined than that of Alexander and Evans, in which an adherent macrophage population can be specifically involved as the significant cell. Nevertheless, Peter and Dawkins conclude that because the production of their cytotoxic effect is dependent on the presence of PHA, which is noted for its capacity to transform lymphocytes, their cytotoxin derives from a lymphocyte population. It is intriguing to note that the type of lymphoid tissue placed in culture was derived from a part of the body which is subject to continuous contact with bacteria and presumably with their endotoxins. It would be interesting to learn whether lymph node cells from "quieter" parts of the body were similarly effective.

The third article, by Harding *et al.*, deals with a more specific phenomenon. Allogeneic (same species, different strain) target cells can be destroyed in culture by immune thymus-derived (T) lymphocytes (Cerottini *et al.*, *Nature*, **228**, 1308; 1970), by cells which produce cytotoxic antibody but which are not directly cytotoxic or by cells which can only attack antibody coated cells (the antibody itself is not lytic in the absence of complement). Harding *et al.* are concerned with the origin of this last kind of cell. They conclude that it is not a cell of thymic derivation because it is still present in normal numbers in animals with much reduced numbers of T cells. These authors also say that their cytotoxic cell presumably attacks not the antigens on the target cell but the antibodies attached to these antigens; it is possible that this phenomenon is specific only in the sense that the antigen-antibody complex is specific.

All these articles add to the information which is accumulating about the reactivity patterns of cells derived from the lymphoid and reticuloendothelial systems. It is to be hoped that eventually they can be placed against a wider context to include consideration of the activities of mast cells, granulocytes and eosinophils, all of which can have non-specific more or less toxic activities.

interior of the supercontinent where they suppose that the influence of moisture-bearing wind currents could not reach. And no moisture means, of course, no glaciation. Similarly with coal deposits. Coal apparently can only form in areas where the minimum annual rainfall is 1,500–2,000 mm ; and yet coal is found in the interior of Gondwanaland. The obvious conclusion then, according to Meyerhoff and Teichert, is that Gondwanaland could not have existed in the late Carboniferous and Permian. This contention is also supported by the presence of marine evaporites in Gondwanaland's interior within 15° of the Carboniferous and Permian poles. Although they do not say so explicitly, Meyerhoff and Teichert's position apparently conceals an anti-continental drift philosophy or at least one which does not allow ancient supercontinents.

It is the view of Meyerhoff and Teichert that a revolution in the concepts of southern hemisphere glaciation has been taking place simultaneously with the revolution in the Earth sciences but that the Earth scientists have been too busy to notice it—and thus one of the props of the new global tectonics has been whipped away. Clearly this is to overestimate the importance of glaciation in the continental drift context. Until Gough's recent article appeared the concept of the large Gondwanaland ice sheet was largely of historical interest, important at a time when evidence for drift was sparse but later superseded by far more convincing evidence. This apart, however, it would seem that the conflict between Meyerhoff and Teichert on the one hand and Gough on the other is essentially one of apparent irreconcilability of different disciplines —palaeontology and geology versus geophysics.

In his reply Gough wryly admits that "as a geophysicist, [he is] an outsider in these geological matters", but nevertheless proceeds to demolish his critics with the confidence of somebody who firmly believes in seeing wood for trees. Thus the existence of the thirty centres of glaciation in their respective positions leads him, with du Toit, to the interpretation that large ice sheets existed over part of Gondwanaland and not to Meyerhoff and Teichert's negative conclusion. The mountain-top ice caps and U-shaped valleys are easy to explain because if ice forms at all in a continent of rugged topography it will do so first on mountain tops. The resulting glaciers would thereby produce radial U-shaped valleys and, if rainfall and freezing continued, possibly continuous ice sheets. Thus the ice movement would be relatively inhibited such that few permanent traces of ice action would be left in the lowlands.

As for the question of rainfall in the Gondwanaland interior, Gough takes the view that Meyerhoff and Teichert are formulating the problem the wrong way round. The starting point must be the existence of Gondwanaland, evidence for which is now overwhelming. The global tectonic evidence was not mentioned by Meyerhoff and Teichert. The presence of interior ice caps does not disprove the reality of Gondwanaland but only the idea that interior rainfall is impossible. The real problem therefore is to decide how, and under what conditions, the interior ice caps formed. In any case it is not clear to Gough that rainfall cannot occur far from continental margins as long as there is suitable topographical relief.

But there is a final irony. In his original article Gough considered for simplicity a continuous ice sheet 2 km thick and 3,000 km in diameter. The fact is that the same mass of ice distributed in lumps over the same area will produce the same stresses except very near the surface. Thus a continuous ice sheet is not necessary at all! Moreover, an ice sheet 2 km thick and only 1,000 km in diameter will produce the same stresses in the lithosphere and the same stresses below its centre but at a lower depth. Thus the smaller sheet actually produces greater stresses in the asthenosphere where the tectonic flow takes place.

This whole argument, of course, is indicative of the sort of exchange which is likely to become increasingly common. The fact is that the revolution in the Earth sciences has been based almost completely upon geophysics, and many geologists feel that their discipline has not always received the consideration it deserves. The job now is to reinterpret several hundred years of geology in terms of the new global framework ; and some friction is only to be expected.

Advances in Calcitonin Research

A RENAISSANCE in calcium metabolism research has taken place since the discovery of calcitonin nine years ago. Underlying this effort is the interest in the treatment of some fifty million people in the world today with bone-losing diseases. These diseases are loosely referred to as "osteoporosis".

The current investigative approach to the treatment of bone loss is the use of substances that inhibit bone resorption. The most popular of these is calcitonin, a hormone from the thyroid. Calcitonin acts directly and immediately on osteoclasts, the cells which resorb bone to inhibit their action. Because bone is constantly undergoing remodelling and replacement, prevention of bone loss, while new bone is continuing to be laid down, should lead to more bone. In next Wednesday's *Nature New Biology,* two letters contribute to the discussion of whether or not this hormone will prove of therapeutic importance.

The first of these contributions, by Anderson and his colleagues in Urbana, Illinois, reports the failure of moderately long-term treatment with porcine calcitonin to alter the retention of strontium-85. This isotope is unique in that its uptake in and release from bone is similar to that of calcium. Anderson *et al.* have measured whole body retention in dogs of this isotope, as a function of bone mineral turnover; and found that calcitonin did not delay its loss. The results are surprising in view of work done elsewhere (for example at the Hammersmith Hospital, London), which has demonstrated that calcitonin increases metaphyseal bone in rats and promotes positive calcium in patients with Paget's disease. In contrast to both growing rats and Pagetic patients who have a rapid rate of bone turnover, bone turnover in normal dogs, however, is less and therefore more closely approximates the rates observed in osteoporosis in man. If the observations reported in next week's issue are true, it may be that calcitonin will not prove effective in preventing bone loss in patients whose rates of bone resorption are not abnormally high.

But in a second letter, Potts and his group at the Massachusetts General Hospital in Boston report that salmon calcitonin is 20–2,000 times more potent than the porcine hormone used in the previous study. Two explanations for this difference are tenable: either the salmon hormone has a greater affinity for receptor sites or it is more resistant to degradation. Potts *et al.* present evidence which supports the second explanation. As measured by radioimmunoassay, salmon calcitonin was found to have a slower rate of disappearance in the dog.

Salmon and porcine calcitonin differ in fifteen of their constituent amino-acids. That the hormones from different species have different rates of destruction introduces a new concept. This concept seems to be as follows: the activity of a peptide hormone is dependent not only on those amino-acids which confer biological activity but also possibly on other amino-acids which affect its rate of destruction. It follows from this that synthetic analogues which further delay degradation may lead to even more potent preparations than are found in nature.

Transport in the Phloem

D. C. SPANNER

Department of Botany, Bedford College, London NW1 4NS

Exactly how nutrient materials travel through the green plant is still a matter for controversy. This review highlights some of the current points of interest.

MANY readers, not themselves botanists, will be aware of the old dictum "up the wood, down the bast". This draws attention to the two long-distance transport processes in higher plants: the movement of water up the wood from the soil supply to the transpiring leaves, and the independent movement of the products of photosynthesis down from the leaves to the roots. Strictly, this second movement, which is chiefly of sugars, occurs rather from regions of supply to regions of utilization, and so over any given portion of the plant axis is not invariably in the same direction. Broadly, however, the dictum is true. It is with the bast or phloem movement that this article is concerned.

The transport of sugars and other assimilates down the trunks of trees—to consider a concrete case—takes place in files of elongated cells making up the phloem. The most important of these cells are the sieve elements. These are living cells with very little content of living substance, disposed end-to-end like drain pipe sections. They are very narrow (typically about 20-40 µm in diameter), with a length about ten times as great as their width, and with the junction of one element and the next not unconstricted (as in earthenware drainage systems) but crossed by the fused end walls of the two elements. The transverse obstructions, which are about 1 µm thick, are pierced by numerous holes of diameter roughly 0.5–1 µm. For this reason they are aptly referred to as sieve plates, and the long files of cells which they cross at intervals of about 0.5 mm as sieve tubes. Down these tubes the assimilate stream flows at the relatively high velocity of about 50 to 100 cm per hour Already it can be seen that here is a difficult problem in fluid dynamics, at least in the case of tall trees; but the problem has in the past fifteen years been made much more acute by the revelations of the electron microscope. Observations have shown that the most obvious content of the sieve elements (at least in the Angiosperms, and perhaps universally) is a fibrous protein, the P protein, which superficially resembles certain preparations of collagen or actin. Furthermore, this material appears in most careful preparations to occupy, fairly compactly, the pores in the sieve plates. If these plates constitute in themselves a considerable obstruction to flow, it is easy to see the problem which arises when their pores appear densely occluded with fibrous material (Figs. 1 and 2).

The discoverer of sieve tubes (Hartig, 1837, 1860) suspected that they were the conducting channels and although controverted, this view has steadily gained ground until today it is almost unchallenged. Recently autoradiography of thin sections has been the most potent factor in the strengthening of this view. Starting with the earlier work of Biddulph[1] using ^{35}S and ^{32}P, improved resolution has been obtained, first with $^{14}CO_2$ incorporated naturally into assimilates, and then with tritiated sugars applied externally to the leaf[2-4]. The difficulty of the technique arises largely from the water solubility of the compounds concerned, but this has been overcome to such an extent that very recently[5] natural ^{14}C-assimilate has been autoradiographed in resin-embedded material cut no thicker than 1 µm. In both the tritiated material (cut at 6–8 µm in paraffin wax) and this ^{14}C material, convincing evidence has been presented that transport is confined to the sieve tubes. Incidentally, labelled and unlabelled sieve tubes occur in juxtaposition[2], suggesting that to some extent they act independently.

Rate and Pattern of Movement

Recent work by Zimmermann[6] has confirmed the generally accepted view of the velocity of transport. The alternation of day and night would be expected *a priori* to produce a rhythmic change in the transport of assimilates, and Huber *et al.* (1937) measured a sinusoidal variation with height in the sugar concentration in the phloem of trees and were thus able to derive a velocity of movement; it was three or four times larger than currently accepted values. Zimmermann reasoned that changes in water potential in the xylem (which is very close to the phloem) would independently affect the sugar concentration. In certain trees he has demonstrated that sucrose, the most usual sugar found in the transport stream, undergoes in the

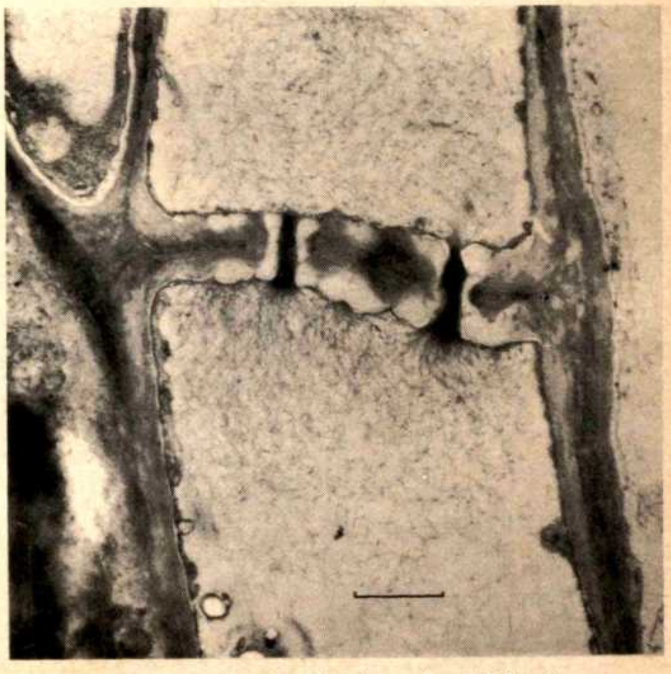

Fig. 1 Longitudinal section of a sieve tube of *Helianthus annuus* showing sieve plate. Fibrils of P protein occupy the lumens and densely occlude the pores. By courtesy of A. W. Siddiqui. (Index line 1 µm.)

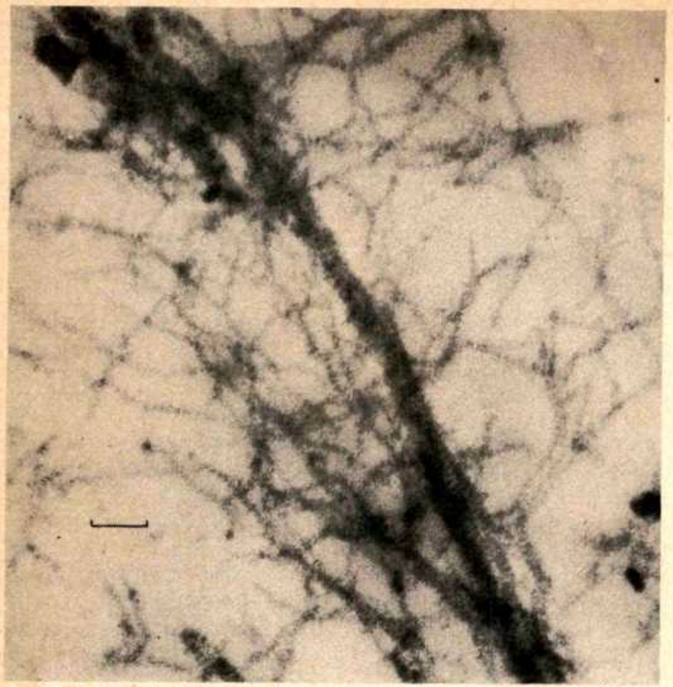

Fig. 2 Banded fibrils of P protein from sieve tube of *Salix caprea*. Note that the bands tend to align themselves transversely. By courtesy of U. Mishra. (Index line 0.1 µm.)

sieve tubes some degree of inter-conversion with the higher sugars raffinose and stachyose. By measuring at various heights simultaneously the ratios between these three sugars he showed that they varied sinusoidally. The velocity of movement implied by these "ratio waves" (30–70 cm h^{-1}) fits well into the accepted range.

On the disputed question of whether or not the sieve tubes are able to conduct in both directions at once (certain suggested mechanisms would allow them to), the past two or three years have provided evidence but no settlement. Eschrich[7] in 1967 reported work on broad bean in which ^{14}C naturally assimilated by one leaf and fluorescein artificially applied to another both appeared in the exudate from an aphid feeding on the stem between them. Because aphids are known to tap single sieve tubes, the evidence was strong for bidirectional movement. But Eschrich himself noted that another explanation was possible: opposite unidirectional movement in parallel sieve tubes with lateral transfer between them. Ho and Peel[8], using ^{14}C and tritiated sugars in willow segments, obtained rather similar results, as did Trip and Gorham[9] using microautoradiography instead of aphids to localize the tracers. But strong contrary evidence turned up in the work of Peterson and Currier[10]. Applying fluorescein at the mid-point of an internode and allowing only a short period (one hour) for translocation, they found on sectioning the stem above and below the mid-point that the dye had moved both upwards and downwards, but only in different bundles. When a longer time was allowed for translocation, however, single bundles were labelled in both directions, almost certainly as a result of the lateral movement of the tracer at the nodal anastomoses. Reluctantly, it must be recognized that this crucial problem, on which considerable effort has been expended, is still unresolved.

Factors affecting the Rate

Although inhibitors have long been used for investigating physiological processes, they have provided a singularly unsatisfactory picture of translocation, and the past few years have confused it rather than otherwise. The chief difficulties arise from the fact that it is hard to discriminate between the transport process itself and the terminal processes in which assimilates are loaded into or unloaded from the conducting channels. In addition the proximity of the xylem, itself capable of long distance conduction, and the propensity of the sieve plates for rapidly sealing themselves off with callose, constitute further difficulties in interpreting inhibitor results in such a way as to decide unambiguously between mechanisms. Harel and Reinhold[11] ensured in soyabean that the vein-loading process was not involved by cutting off the ^{14}C-treated leaflet before the introduction of the inhibitor dinitrophenol (DNP). They found, however, that not only was the transport not inhibited, but downward movement to the roots was promoted. This evidence contradicts previous conclusions. In a well argued case the authors interpret their results as support for the Münch hypothesis (discussed later), though it is not clear how the opening of sieve tubes at their upper ends could leave the pressure gradient (on which the Münch theory relies) unimpaired; nor how they decided against movement throughout the xylem to the roots, a distinct possibility with the likely disturbance of root function through DNP and an overhead water supply. It is an indication of the complexity of the problem that at least two other factors need to be considered before the results can be interpreted confidently—the vascular anatomy, and the effect of the treatment on sieve plate callose. For strangely, in certain circumstances the laying down of callose can accelerate transport[12], a possible consideration in Harel and Reinhold's results.

Low temperature is another factor which has been investigated fairly recently. A striking feature of the phenomenon is that it only requires cooling of a short length of axis (say 2 cm) to reduce drastically the mass transfer rate[13]. Furthermore, if the low temperature is maintained, the subsequent behaviour of the plant varies. With plants acclimatized to cold regions the rate may recover to its previous value fairly quickly, whereas with plants from warmer regions it remains low. In the latter case, restoration of the cooled portion to ambient temperature is followed by recovery in mass translocation rate after a certain time. Geiger considers possible mechanisms for these effects. With naturally cold climate plants the recovery in rate when the axis is held at a low temperature (0.5° C) takes no longer when 8 cm of axis is cooled than when 2 cm is; he argues that this tells against the recovery being due to a build-up of the concentration differential over the cooled region, presumably because a bigger differential would be required over the longer region, and this would take longer to establish. But over the small distances involved and with sugar transport as large as it is, this argument is not so cogent as it seems at first.

It would be natural to suggest that the slow-down caused by chilling is due to a decrease in the rate of the metabolic energy supply. This interpretation would favour the electro-osmotic theory, since unlike the Münch hypothesis its energy supply is mediated all along the route, and not merely at the ends. Geiger, however, suggests an alternative explanation: that the resistance of the transport channels is raised by the chilling process by changes in the sieve tube organelles. But a ten-fold increase is required, and it seems unlikely that the sparse contents could manage this unless the changes took place in the vicinity of the sieve plates. Additional callose, and a denser plugging of the pores with P protein, seem obvious claimants for investigation. It remains possible, however, that the primary cause is a decrease in the rate of supply of metabolic energy. The electro-osmotic theory would then explain recovery in terms of a re-adjustment of the pore mechanism.

Sieve Tube Contents

The contents of the sieve tubes have remained a source of interest, especially those elements which can be considered part of the mechanism, rather than part of the translocation stream. The content of ATP, already known to be fairly high from the work of Kluge and Ziegler[14], has been confirmed using aphid stylet extract of willow[15], and more recently by measurements on the copious phloem exudate of *Yucca* inflorescence[16]. All reports give a fairly high concentration

(0.6–1 mg ml.$^{-1}$ or about 0.002 M). No doubt this is significant for the callose closing reaction, and perhaps also for the flow mechanism. Phosphatases have been further reported on. In view of the slightly alkaline reaction of sieve tube sap the incidence of alkaline phosphatase in mature *Pisum* sieve tubes[17] is interesting, though most of the reports have been of acid phosphatases. Zee[18] found no acid phosphatase activity in the "slime" of *Pisum* (contra a report[19] for *Tilia*) though there was activity in the plasmalemma and endoplasmic reticulum of mature tubes. Robards and Kidwai[20] reported ATPase activity at *p*H 7.2 in immature phloem and ray cells; lead deposits occurred on both the inner and outer edges of the plasmalemma as well as elsewhere. Yapa (unpublished) has found ATPase activity at *p*H 7.2 in the plasmalemma of mature sieve tubes.

But of all the sieve tube contents the one of major interest has continued to be the famous slime, now appropriately renamed P protein[21]. Its proteinaceous nature has been inferred from staining reactions, ultrastructural appearance, enzyme digestion (Yapa, unpublished results) and chemical analysis of phloem exudate[22], and there seems little doubt that the banded fibrillar material so often seen in electron micrographs is pure protein, probably of a rather chemically resistant nature. It seems to be the case that ontogenetically it originates from "slime bodies" often composed of bundles of more or less parallel tubular elements, resembling microtubules but distinct from them[23]. There seems to be some diversity in the tubular-type slime bodies, and the slime bodies may in some plants be composed of fibrils from the first[24]. The sieve tubes may be the sites of P protein production for some time after maturity sets in; and P protein, or something similar to it, may be produced in ways other than from typical slime bodies. For example, it may come in addition from protein crystals in Leguminosae[25] and from sieve tube plastids in certain Caryophyllales[26,27]. In primary tissue the P protein seems to be connected with peculiar cell organelles called "spiny vesicles"[28]. Later studies seem to have confirmed this idea[29]. If so, then it would seem to be the case that in protophloem, adjacent parenchyma cells assist in the production of P protein for the sieve elements. Furthermore, the occurrence of typical P protein in the plant kingdom seems to have been extended more firmly to the monocotyledons[30], so that when everything is considered, the conviction that this material fulfils some essential role in the translocation process has been strengthened.

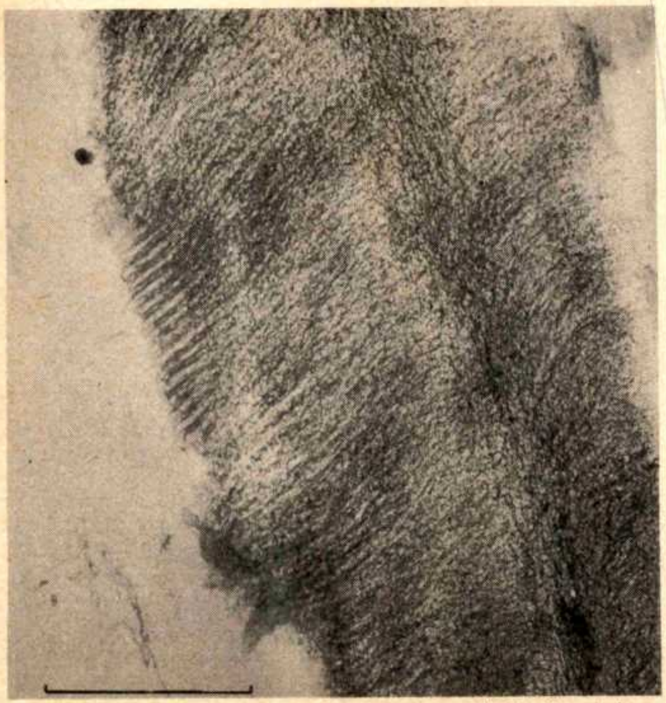

Fig. 3 Membrane stacks in close contact with the sieve tube wall in *Nymphoides* petiole. By courtesy of R. L. Jones. (Index line 0.5 μm.)

Of the other constituents of the sieve tube I shall mention only the endoplasmic reticulum (ER). Recent studies have confirmed this to be a fairly abundant element of the cytoplasm in mature tubes[31]. It is frequently present in parietal "stacks", with the constituent membranes lying either parallel to the tube wall or set almost at right angles to it (Fig. 3). Often it occurs in curious convoluted configurations, like papier-mâché egg boxes stacked within one another[32]. It usually seems to be anchored closely to the wall, and sometimes when the membranes stand perpendicular to the latter they seem to be continuous with dark lines within it. Certainly the thick sieve tube wall, the cellulose fibrils of which probably run in shallow spirals and which seem to contain little cementing substance, often has pronounced radial striations in longitudinal section. These appearances have led to the suggestion[33] that the ER stacks are really plasmalemma which in the turgid cell is buried in the cellulose wall, but which emerges more or less rapidly (hence the variety of configurations) into the lumen on collapse of turgor. Whether this unorthodox idea can be substantiated remains to be seen. Attempts to fix and section plasmolysed sieve tubes have not so far yielded supporting evidence.

The Question of Mechanism

In this short review I shall consider only two mechanisms (though others are being canvassed); the Münch or pressure flow hypothesis[34], which considers movement in the sieve tubes to be due to a gradient of hydrostatic pressure; and the electro-osmotic hypothesis, which invokes electrical forces called into play at the sieve plates by the active secretion of potassium ions[33,35]. Both involve mass flow, and both therefore have a similar stake in the observation (or otherwise) of simultaneous bi-directional movement, which was discussed inconclusively earlier. One important issue on which the theories differ is in their relation to the state of the pores in the sieve plate. If the natural functioning condition of these is as Fig. 1 indicates, then simple calculation shows that the pressure gradient required by the Münch hypothesis is far too great to be realizable in practice—of the order of several hundred atmospheres per metre[36]. On the other hand, there is no problem here for the electro-osmotic theory—it positively requires that the pores be occluded in some such way as the micrograph shows. On the other hand, this theory runs into difficulties of its own, particularly that it seems to imply a very high current density for potassium ions, perhaps as high as 1 A cm^{-2} of sieve tube cross-section. In this connexion the suggestion of a greatly expanded plasmalemma in the sieve tube is important, for secretion of the ion across this membrane would be the resistive as well as the energy-transducing step.

The conflict between the two hypotheses centres largely on whether micrographs such as Fig. 1 are faithful representations of the functioning sieve plate. It must be emphasized that the sieve tubes have high turgor pressure coupled with relative ease of longitudinal movement; thus any attempt to cut into them or manipulate them for examination in the electron microscope runs the risk of causing violent axial surges. P protein being present in the lumen, such surges will arguably carry it to and through the sieve plates. The supporters of the Münch hypothesis argue that the pores in the functioning tube are unoccluded with P protein. Fig. 1 accordingly shows an artefact; it is a difficult matter (though micrographs have been obtained) to record faithfully the functioning condition. That is why the pores so rarely appear open. The supporters of the electro-osmotic theory take a different view. They maintain that much of the evidence adduced to support the "artefact" view in fact does almost the opposite. Even the very narrow and exposed sieve tubes of small leaf veins, so narrow that the sieve plates may have only one pore, show the same sort of plugging[37]. The same can be said, they point out, of the short curved sieve tubes of callus tissue[38]. Of course, every device of chemical or physical manipulation (such as freeze drying, freeze etching and prior wilting or boiling) has been pressed into service to resolve the issue, but neither side seems disposed to give way[39,40].

It is often urged that the use of macroscopic equations of viscous flow is misleading in the case of channels which might be no more than 100 Å wide, so that the argument about the state of the pores is for the moment pointless. But some evidence indicates that in very fine channels the viscosity of water does not drastically fall; on the contrary it seems to rise. Churayev, Sobolev and Zorin[41] found an increase of 40% in quartz capillaries of 0.04 mm radius. Thus the problem is a real one.

The special evidence for the Münch hypothesis is not particularly strong. It turns mostly on its simple physical character. Also, it can allow the ready transport in sieve tubes of large particles like viruses[42]. On the other hand, the electro-osmotic theory has numerous arguments of an indirect nature to recommend it. It is much more physiological, and can take in its stride any well authenticated evidence for an effect of poisons, anoxia or low temperature. It offers a major role for potassium, hitherto without one; and it also makes substantial suggestions for the functions of P protein, membrane stacks, companion cells and the thick sieve tube wall. More direct (though hardly decisive) is the experimental evidence for a saw-tooth profile of electrical potential[43] in the sieve tubes, as required by the theory; and that potassium deficiency too small to cause visible symptoms apparently has a primary effect in lowering translocation[44].

Two recent approaches to the investigation of mechanism should be mentioned. Fensom and his collaborators[45] have applied Nomarski interference optics to the cinematography of functioning *Heracleum* phloem. No actual translocatory movement of particles was visible across the sieve plate, but an unusual type of particle movement (probably of starch grains) was reported. But in view of the reports that the release of starch grains from plastids in sieve tubes is probably an injury effect one needs evidence that the sieve tubes recorded were functioning normally. Milburn[47], in what he described as a "lunatic fringe" experiment, followed up a clue from Bose and tried the effect of simple massage (squeezing gently between finger and thumb) on the stem of young plants of *Ricinus*. Repeated at intervals three times a day for several days, this had the remarkable effect that when an oblique incision was made into the bark the phloem exuded copiously, up to 1 ml. of sap being obtainable from a single incision in a plant 20 cm tall, with little progressive decrease in concentration. Milburn interprets this phenomenon as follows. The sieve plate pores are normally open. Massage triggers an automatic sealing mechanism which operates to block the pores (and so serves in severed plant organs a function analogous to blood clotting). Subsequently an anti-sealing mechanism frees the pores and enables translocation to re-start. Repeated massage exhausts this double reaction so that when an incision is finally made the plant is defenceless and bleeds phloem sap profusely. Milburn rejects the obvious suggestion that massage cumulatively disrupts a natural state of affairs illustrated by Fig. 1, on the grounds that if a plant which has been induced to bleed profusely is massaged at the point of exudation, the exudation stops within minutes or seconds. Temporary application of pressure 2.5 cm from the incision on both sides acts similarly. My interpretation would be, on the contrary, that the whole phenomenon supports the *prima facie* understanding of Fig. 1. Massage ejects the P protein plugs from the sieve pores, and repeated massage prevents their re-establishment and furthers the dislocation. In the rapid exudation following subsequent incision the disorganized P protein is being hurried through the sieve plate pores; temporary slackening of the flow by finger pressure enables it to build up in front of one or more sieve plates so that on release an effective blockage remains. This interpretation seems less contrived than invoking a sealing–unsealing mechanism of unspecified character which, thrown out of gear by massage, can nevertheless recover sufficiently when exudation is in full operation to respond to pressure of the fingers.

Future Developments

Taken by itself it is hardly disputable that the electron microscope evidence supports the view that the sieve plate pores are plugged in a carefully structured fashion with P protein fibrils. The difficulty of reconciling this picture with the physiological facts leads to the impasse. Thus after more than a century of investigation there is no agreed answer to the question of how the sieve tubes conduct. What developments may be expected in future work on the problem? On the anatomical side we may anticipate a wider range of comparative studies with the electron microscope, including more emphasis on perennial monocotyledons and the lower vascular plants, and on freeze etching and other recent techniques. The sieve tube wall will probably be examined carefully. On the biochemical side, the chemical and physiochemical characterization of P protein will be an obvious target, and also the nature of the callose-triggering reaction and the metabolic function of high energy compounds in the sieve tubes. Microelectrode techniques and the movements of potassium will certainly fit into the picture. Finally, on the level of whole plant physiology, quantitative data for the movement of tracers of different kinds will probably be combined with computer analysis of more adequate model systems. With patience we may hope to see fuller light on this intriguing phenomenon.

The Space Scars of Earth

PETER M. MILLMAN
National Research Council of Canada, Ottawa, Ontario

There is some evidence for a meteoritic origin of craters in the Earth's surface. In this article the characteristic features of impact scars are discussed with the help of some examples.

THE two planetary bodies whose surfaces can be seen best from Earth and from spacecraft are the Moon and Mars. A dominant characteristic of both surfaces is a complex of circular craters of widely varying size and there is now considerable evidence that most of these craters resulted from the infall of the smaller, and less massive, bodies of the solar system—asteroids, meteoroids and possibly comets. We see the primary and secondary impact scars of these collisions with material from interplanetary space. It can be argued that the Earth should have suffered a similar celestial bombardment, and evidence of this is now growing rapidly, but because the Earth's surface is subject to many changes initiated by the atmosphere and oceans, the impact craters often have to be untangled from a maze of other features that may hide them from all but the persistent investigator.

Increasing Attention

It is rather surprising that in the past the detection of impact scars on Earth attracted little attention from most geologists. This situation is now changing rapidly and new information is becoming available in such profusion that any review of the subject rapidly becomes out of date.

Near the end of the last century there were tentative suggestions that the formation of certain depressions on Earth might have a connexion with meteoritic impact. G. K. Gilbert, for example[1], discussed this possible origin for the crater in Arizona—then known as Coon Butte—and for Lonar Lake in India. He discarded the hypothesis, chiefly because of a lack of understanding of the tremendous explosive force inherent in an impact at typical interplanetary collision speeds (15 to 25 km s^{-1}).

The scientific study of terrestrial impact features can properly be dated from the presentation of two papers[2,3] before the Academy of Natural Sciences in Philadelphia on December 5, 1905. Both Barringer and Tilghman put forward in detail numerous reasons why Coon Butte should be considered a meteoritic crater and not the result of volcanic action or a steam explosion. In the face of considerable opposition to his theory, Barringer followed up his original paper with a continuing study of the Arizona crater until his death in 1929; in recognition of his pioneering work this feature is now officially named the Barringer Crater. (Barringer also has a crater on the Moon named after him.)

It was not until 1926 that the crater at Odessa, Texas[4,5], was suspected to be of meteoritic origin and in the next few years impact features were recognized in a number of other sites[6]. Spencer[6] reviews accounts of twenty-eight craters in seven locations, all of which are now considered to be meteoritic in origin and to contain associated meteoritic material. Spencer also mentioned the Tunguska event in Siberia on June 30, 1908, but this is not generally considered to have produced recognizable impact craters on the Earth's surface[7].

Cryptovolcanism

The second phase in the study of terrestrial impact scars commenced with a series of papers[8-10] by J. D. Boon and C. C. Albritton who gave reasons why certain geological structures, previously called cryptovolcanic, should be considered of impact origin. In this case the argument was not as direct as for the craters listed by Spencer. The ages of the cryptovolcanic features were measured in hundreds of millions of years so that little remained of the original form, and any meteoritic material that might have been scattered in the area had long since disappeared. A common characteristic of these generally circular structures is the evidence of strong explosive action at a period that did not coincide with the age of the rocks involved. A wide acceptance of the views of Boon and Albritton came only after recent advances in the knowledge of highly shocked minerals. Eight of the nine structures listed by these authors as possibly meteoritic are now generally accepted as impact scars.

Canadian Studies

The third phase in the study of meteoritic craters did not start until 1950 when V. B. Meen of the Royal Ontario Museum led an expedition to Northern Ungava, Quebec, to investigate a circular lake that seemed to be a geological anomaly in the peninsula[11]. This feature, now named the New Quebec Crater, was pronounced meteoritic by Meen. Other discoveries among the ancient rocks of Canada were made soon afterwards, many as a result of a systematic search of air photographs organized by C. S. Beals[12] at the Dominion Observatory, Ottawa. Beals also introduced a new technique in the study of these ancient structures; various geophysical measurements were carried out systematically in a coordinated programme and then combined to give an overall picture. A good example is the investigation of the Brent Crater[13], which included aerial photography, topographical survey, surface geology, deep core drilling, and surveys by magnetic, seismic and gravity techniques. Brent has been used as a type example for comparing and assessing data secured in various ways. About twenty Canadian features are now being studied by these comprehensive geophysical methods[14].

The latest developments in the study of meteoritic impact features have arisen from the recognition of several definitive

Table 1 Identification Criteria for Impact Craters

Form and structure	General circular form, depression with raised rim, radial fracturing and rim strata uplift, central uplift.
Meteoritic material	Presence of meteorites, nickel–iron spherules, iron shale of meteoritic origin.
Rock breccia	Impact produced breccia—on surface with fragments approaching metre sizes or larger, in drill cores with fragments of centimetre sizes, in rock samples as micro-breccia or suevite.
Shatter cones	Cone shaped formations found in a variety of rock types.
Mineralogical shock evidence	Numerous small scale and microscopic characteristics ranging from planar features and deformation discontinuities to fused glassy fragments with vesicles and streaks, forming a pumice-like material with lechatelierite.
Impact melts	Igneous materials—rocks, lavas, glasses, formed by impact melting.

characteristics, both microscopic and macroscopic, of highly shocked materials. As early as 1946 Dietz[15] pointed out the value of shatter cones as shock indicators and since 1960 further knowledge of shock metamorphosis has accumulated rapidly[16] as a result of X-ray analysis and work with the microscope and the electron microprobe. The application of these new techniques to samples recovered from suspected impact sites has made it much easier to distinguish between structures that have only a superficial resemblance to impact craters and those that are genuine impact scars.

Geophysicists, geologists and astronomers now have at their disposal a wide variety of criteria for deciding the origin of a possible terrestrial impact feature. Some of the more important of these are shown in Table 1 but the list is by no means exhaustive. The overall picture of any site and the possibilities of origins other than impact must be considered carefully in coming to a conclusion in any given case.

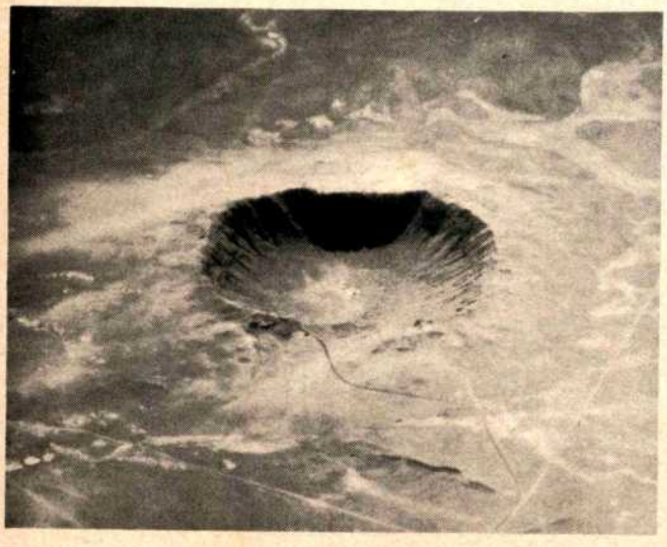

Fig. 1 The Barringer Crater, Arizona, diameter 1.2 km, photographed from the north near local noon on January 29, 1967. The polygonal form of the crater rim, seen in so many lunar craters, is quite evident.

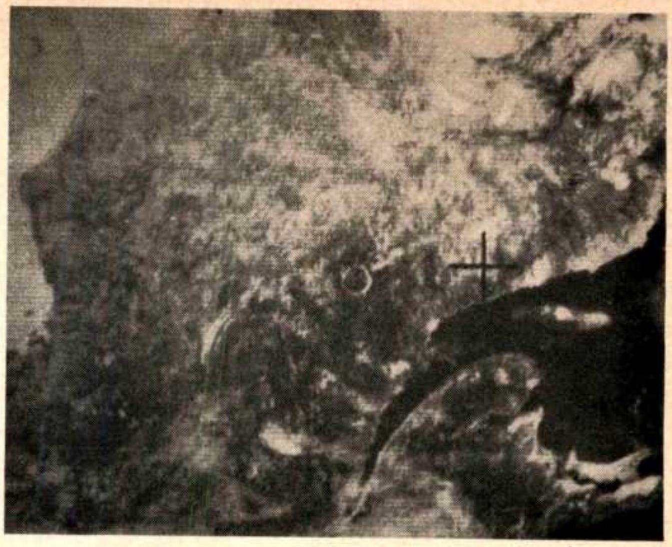

[Photo: Canadian Meteorological Service]

Fig. 2 The Manicouagan Crater, Quebec, diameter 60 km, photographed from the ESSA-8 satellite on March 18, 1969. The crater appears at centre while a much larger feature, the Hudson Bay arc, is at upper left. This arc is still on the list of suspected impact scars[34].

Energy Release

The shape of a newly formed impact crater is caused by the sudden release of the kinetic energy of the impacting mass within a small volume somewhat below the original impacted surface. Matter will be ejected approximately equally in all directions and the impacting meteoroid will be broken up, pulverized and partially vaporized in the process. The result is a bowl shaped depression with a raised rim and, in some cases, a central uplift. Typical energies range from $\sim 10^{20}$ erg for a crater of diameter about 1 km to $\sim 10^{30}$ erg for a diameter of 50–100 km.

The form of relatively recent terrestrial impact craters corresponds closely with the youngest craters on the Moon and craters produced by artificial explosions on the Earth. The best example of a comparatively fresh impact scar is the Barringer Crater (Fig. 1) which has been preserved by the arid climate of Arizona from excessive erosion and sedimentation during the 30,000 or more years since it was formed. The outward tilting of the normally horizontal rock strata is very evident, even to the casual observer, and one-sixth or more of its original depth has probably been filled up. In the case of the much older Canadian craters in the same size range, the original depression has often been completely filled by sediments tens or hundreds of millions of years old. Geophysical methods introduced in the 1950s make it possible to outline the original crater depth and the brecciated volume beneath the crater floor in these instances. The old craters of a category in which the original diameter was more than several kilometres normally show a central uplift. In many cases, the original crater has been filled and the rim eroded, but the central uplift is the one dominant feature which remains clearly visible. Some details of the central uplift in terrestrial craters are not yet completely understood but, in broad terms, the uplift may be ascribed to a combination of post-impact slumping of the crater walls, isostatic adjustments, and elastic rebound in the subsurface rock layers[17]. The mechanisms of central uplift will have a greater effect in the larger craters, since here the energy of impact is in a higher ratio to the energy required to deform the geological strata. One of the large Canadian impact scars, Manicouagan (Fig. 2), demonstrates well the peripheral trough which is often the most conspicuous structural feature in deeply eroded ancient craters.

Meteoritic Evidence

The presence of meteoritic material was once considered essential for the positive identification of an impact crater, and meteorites have been associated with all the smaller and younger impact features. Nickel–iron spherules of several types in the millimetre size range were first found in 1946 by Nininger[18,19] at the Barringer Crater, and have been found more recently at a number of sites where meteorites have not yet been located. The manner of formation of these spherules is still a matter for discussion but there is no doubt that they are a product of the original meteoroid[20]. In the case of the very old impact features identifiable meteoritic material has not often been found. Calculations of the diameters of the meteoroids producing these craters have varied from 1/20 to 1/30 of the crater diameter for a stony meteoroid, so the meteoroid volume would have been much less than 10^{-4} times the volume of terrestrial rock involved. Surface meteoritic material would not have remained *in situ* for millions of years, and probably only the nickel–iron portion of this material would be identified in the drill core sampling. Only a very small fraction of the total volume is studied in drill core methods and it is not surprising that there is little direct evidence of the original meteoroid.

Evidence of the shattering force of space impact may be seen in the broken rock fragments commonly associated with space scars. Barringer[2] called early attention to the large-scale debris scattered around the crater that now bears his name. Drill cores, such as those from the Holleford Crater[21], illustrate vividly the type of rock breccia that is found below the crater floors. Breccias of an even finer grain size can be identified with a microscope[22].

The work of R. S. Dietz on shatter cones has already been mentioned and he has recently reviewed their occurrence at terrestrial impact sites[23]. These cone-shaped structures are formed by shock in a variety of rock types at pressures from 20 to 100 kbar, much greater than the pressures usually ascribed to terrestrial volcanic mechanisms.

Other mineralogical shock evidence is relevant to even higher pressures[24] and at shock pressures between 100 and 300 kbar planar features (closely spaced fine parallel lines) develop in quartz, plagioclase and other minerals. An example of this microscopic structure in quartz is shown in Fig. 3. Apart from the planar features there is other evidence of deformation, for example, slip bands, kink bands and deformation lamellae. At pressures from 300 to 500 kbar there are still planar features and also the highly shocked phases of SiO_2, coesite and stishovite. In this pressure range undisturbed

mineral crystals begin to change to the disordered or amorphous phases and at 500 to 650 kbar glasses containing vesicles and streaks are formed and most of the original texture of the crystalline rocks is destroyed. At pressures approaching 1,000 kbar and temperatures of 5,000 K complete melting occurs.

High temperatures are developed in an impact event, particularly the larger terrestrial features. The surface rocks melt and leave igneous materials in the form of glass in mixed breccias, layers of rock melt, and intrusions into basement rocks below the crater. Dence[25] has noted these melts at about forty impact sites.

General Characteristics

There is no single standard listing of terrestrial impact craters and a number of lists (refs. 26–33 and R. W. Barringer, personal communication) have, for example, been published since 1960. Many suspected sites are now known at which a full scale field study has not yet been possible and most of these are therefore in the doubtful category at present. To illustrate some general characteristics of the Earth's impact scars, I have selected from these lists and from more recent literature 62 sites which include the best authenticated examples of impact craters. Preference has been shown in this selection for evidence of high shock effects. The 62 sites include 112 individual craters with diameters ≥10 m, an arbitrarily chosen lower size limit. The geographical distribution of the 62 sites is summarized in Tables 2 and 3.

Estimates can be made for the original diameter of each crater and for its age. Only small accuracy can be achieved with individual craters, particularly when their age is large, but the overall statistical picture is probably free from serious systematic errors. Diameter and age estimates for the 112 craters have been plotted in Fig. 4—the eight groups of multiple craters have been separately identified.

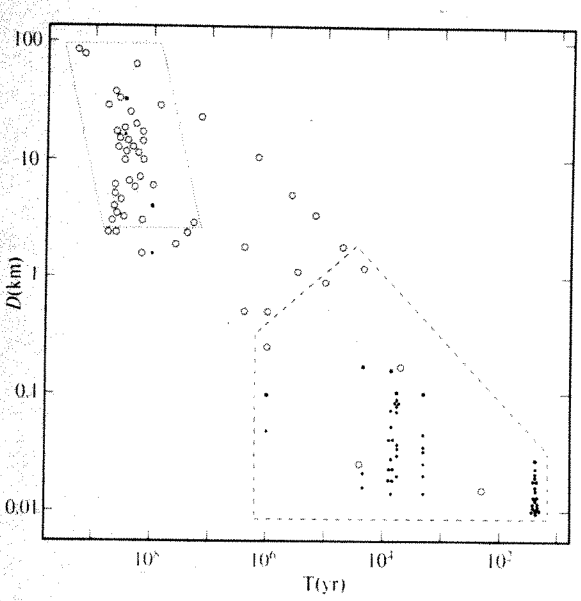

Fig. 4 A logarithmic plot of the estimated original diameter of each crater, *D* km, plotted against the estimated age, *T* yr. Meteorites have been found associated with all craters in the area enclosed by dashed lines. Central uplift is present in three-quarters of the craters in the area enclosed by dotted lines. ○, Single crater; ●, crater group.

One must be careful not to draw unwarranted conclusions from Fig. 4. It has been plotted more to show the distribution in age and size of the recognized impact features on Earth, than to demonstrate any important relation. Even though the logarithmic scale tends to crowd points to the left of the diagram, the apparent lack of large recent craters is probably a real effect; massive space impacts were undoubtedly more common when the solar system was younger. The lack of old small craters is caused by erosion and obliteration.

If the assumption is made that the majority of large lunar craters were formed by impact, it is natural to compare the numbers found per unit area on the Moon with the numbers found on Earth, as both Moon and Earth have been subjected to the same interplanetary environment. An approximate count indicates that the crater density on the Moon is several orders of magnitude greater than it is here but the impossibility of estimating the terrestrial obliteration effects over hundreds of millions of years makes a quantitative comparison almost useless. It can safely be said, however, that lunar crater statistics suggest that many more terrestrial impact features will be found if we look hard enough for them. At a time when a very large effort is being expended on the study and interpretation of lunar surface materials, the analysis of the corresponding materials from terrestrial impact sites is an essential concomitant activity.

I acknowledge many profitable consultations with Mr M. R. Dence.

Circular Polarization: Jupiter and Other Planets

JAMES C. KEMP* & RAMON D. WOLSTENCROFT
Institute for Astronomy, University of Hawaii, Honolulu, Hawaii 96822

JOHN B. SWEDLUND
Department of Physics, University of Oregon, Eugene, Oregon 97403

Circular polarization of scattered light from Jupiter has now been studied during a recent opposition of the planet, showing changes in the sign of the north and south polar values indicative of a non-magnetic origin for the polarization. Preliminary observations on Mars, Venus, Mercury and the Moon demonstrate the generality of this effect and its potential usefulness.

SINCE our discovery of circular polarization in the scattered light from Jupiter[1], we have continued the observations through the period of opposition. A reversal in sign of the predominant "polar" effect can now be reported, clearly substantiating a scattering model[2] as opposed to alternatives such as magnetoreflexion. We have also observed what are believed to be analogous effects, although sometimes with differing signs and other interesting features, in the cases of Mars, Venus, Mercury and the Moon. The data in these cases are illustrative only, but they show that the phenomenon is general, that it can be measured and that it provides new information for planetary astronomy.

All these observations except those on the Moon followed a scheme shown in Fig. 1*a*. Fractional circular polarizations Q_0, Q_N, and Q_S were measured in light from the whole planet, the northern hemisphere, and the southern hemisphere respectively. North and south in all cases are heliocentric directions (normal to the plane of the solar system) rather than terrestrial or planet-axis directions. For Q_N and Q_S a large aperture stop was used at the telescope focal plane, two to three times the diameter of the planet image; the stop edge served to bisect the planet approximately as shown. In the earlier Jupiter measurements[1], Q_N and Q_S were measured instead with a small stop, about half the diameter of the image of the planet and centred inside the planet disk near one or the other of the poles. The new choice gave very similar values (as checked on Jupiter) and reduced the problem of guiding, as the principal drift was in right ascension. It should be approximately true that $Q_0 = \frac{1}{2}(Q_N + Q_S)$; in the data reported this is not always so, notably in the case of Mercury, because of telescope guiding errors. Contamination by sky effects was always checked and was possibly significant only in the case of Mercury. Spurious signals due to the indirect effect of linear polarization were cancelled out routinely, as in previous work, by taking the algebraic average of readings made with the polarimeter at relative orientations 0° and 90° about the telescope axis. The bulk of the measurements were made on one of the two 24 inch telescopes at Mauna Kea Observatory; on Jupiter, Venus, and Mars, comparison measurements were made with the 88 inch telescope, with entirely consistent results.

With the exception of Mars we have confined virtually all the measurements to a pass band about 500 Å wide (half-transmission points) centred near 6800 Å, for reasons indicated earlier[1]. Actually the spectral coverage can be readily extended.

Jupiter

The crossover of Q_N and Q_S (hemispheric polarizations) through zero at opposition of Jupiter is apparent in Fig. 2. The abscissa here is the phase angle φ between the Sun-planet and Earth-planet directions. (This angle was denoted ψ in the earlier papers[1,2]; we have changed notation to conform to that of Pospergelis[3], whose laboratory work will be discussed here.) Before opposition, or when the planet is a "morning" object, φ is negative. We observe that Q_N goes almost linearly through zero at $\varphi = 0°$; this is the behaviour expected over the small range of φ represented here. A sur-

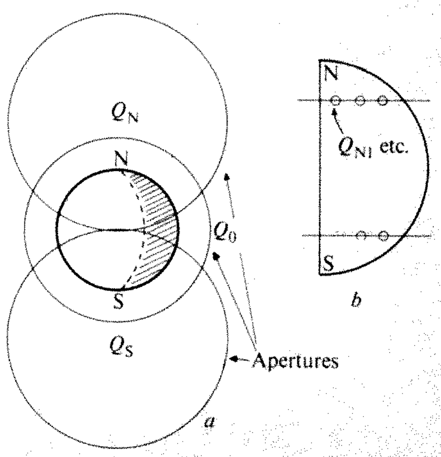

Fig. 1 Observing schemes for measuring the circular polarization of the whole planet Q_0, and hemispheric values. The lighter circles in *a* are telescope aperture stops. *a*, Planet; *b*, Moon.

---

*On leave from Department of Physics, University of Oregon, Eugene, Oregon 97403.

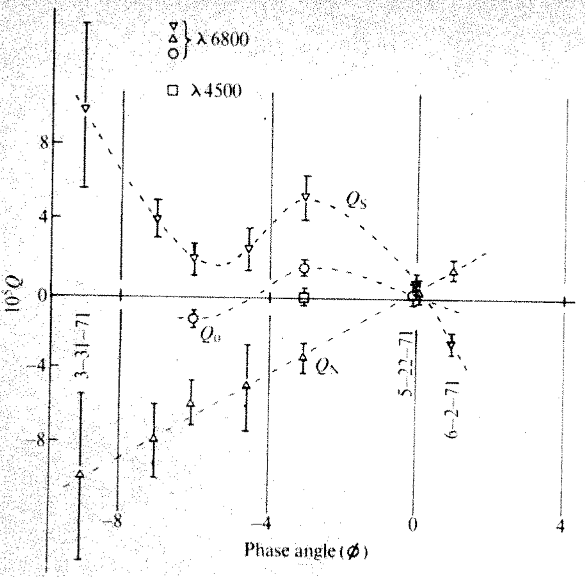

Fig. 2 Fractional circular polarization of Jupiter during the period of opposition, May 23, 1971. Observation on June 15, at $\varphi = +4.5°$, after this figure was drawn, gave $Q_0 = +1 \times 10^{-5}$, $Q_N = +5 \times 10^{-5}$, and $Q_S = -6 \times 10^{-5}$, all at $\lambda = 6800$ Å.

prising peculiarity, however, is seen in Q_S—a kind of S-shaped undulation, superimposed on the overall crossover through zero. This undulation is also reflected in the polarization, Q_0, of the whole planet. The cause of this fluctuation cannot be a general north–south asymmetry with respect to absorption; that would lead merely to a difference in slopes between the Q_S and Q_N curves. One question is whether the Q_S anomaly can somehow be related to the presence of the Red Spot in the southern hemisphere. We did not monitor Q_S and Q_N over a complete cycle of the planet's rotation cycle, at each orbital phase φ. But in one case, the observations of May 10–11 ($\varphi \simeq -3°$), we measured the quantity Q_0 periodically over a five hour period, during which the Red Spot traversed the front of the planet and disappeared behind the west limb. Q_0 did not change by more than the measurement uncertainty of about ±20%. The cause might instead be related to the orientation of Jupiter's spin axis, which is inclined about 3° from the normal to the orbit plane and which, during the period of this opposition, was such that the south pole was tilted toward us by the maximum amount.

In the observations of May 10–11 when Q_0 showed a maximum positive value, we also measured this quantity with a broad blue filter, having a pass band of 1000 Å centred at about 4500 Å. The null result $(0.0 \pm 0.5) \times 10^{-5}$ is consistent with the notion that ellipticity requires absorption. Studies in the near infrared, where there are strong methane bands, will be expected to show large Q values.

No further results were obtained on the interesting localized effects noted earlier in the area of the Red Spot[1]. These must await construction of an improved arrangement for guiding the telescope which will facilitate signal-averaging on small areas of the image.

Venus and Mercury

Having a dense atmosphere as does Jupiter, Venus showed the polar scattering effect, as expected, with the same signs of Q_N and Q_S as Jupiter for the same sign of φ. (In this instance Venus was a morning star, with negative φ as with Jupiter before opposition.) What one might call the elliptical scattering power Q/φ (or $\partial Q/\partial\varphi$) is notably smaller (Table 1) than for Jupiter, at the same measuring wavelength in the deep red.

The single result on Mercury showed the same sign of the polar effect as for Jupiter ($\varphi < 0$) and Venus, but with a surprisingly large asymmetry that is a large Q_0, as shown in Table 1. As with observations of other types on Mercury[4], this measurement was a precarious one which had to be accomplished within a period of less than 30 min while the planet was high enough to be free of horizon effects, yet before sunrise. Seeing conditions were just adequate to permit us to discern the halfmoon-like image, and resolution of the planet into north–south halves (Fig. 1*a*) was done with only fair accuracy. We were aware that an elliptically polarized morning sky could in this case be a spurious cause of the asymmetry, adding, for example, to Q_S and acting to cancel Q_N. A brief test on adjacent sky tended to rule this out, and we believe the asymmetry is real. Whether or not that is so, the polar difference Q_N–Q_S should be independent of sky effects and clearly has the same sign as in the case of Venus. We will comment later on the significance of this sign.

Mars

A striking wavelength-dependent asymmetry was observed in the case of Mars, shown in Fig. 3. In the deep red, the circular polarization seems to approach the ideal polar asymmetry, $Q_N = -Q_S$, although with signs opposite to those of Jupiter and Venus. In the blue, however, the polarization on both poles was overwhelmingly negative. On the basis of the visual appearance of the planet on the dates of the observations, some kind of asymmetry could indeed have been anticipated. The Martian season corresponded to spring in the southern hemisphere, the south pole being tilted toward the Sun with the south polar cap a very dominant feature. A consistent, although quite tentative, explanation for the behaviour of Q_N and Q_S is as follows. At long wavelengths the atmosphere is unimportant, and the scattering is characteristic of a solid surface. That a solid surface can in fact give a polar effect of the sign observed, for the orbital phase angle obtaining here (−40°), will be indicated later. In the blue, on the other hand, there is appreciable atmospheric absorption, the Q values tending to switch over to the "Jupiter" signs. But the albedo of the south polar cap is so large that most of the light from the south comes from solid-surface reflexion, washing out the oppositely polarized flux associated with atmospheric scattering in that region. In the blue, therefore, the atmospheric sign only achieves dominance in the north, where the mean albedo is low.

Uranus and Neptune

Data for Q_0 for Uranus and Neptune are included in Table 1, but are to be taken merely as upper limits. They represent

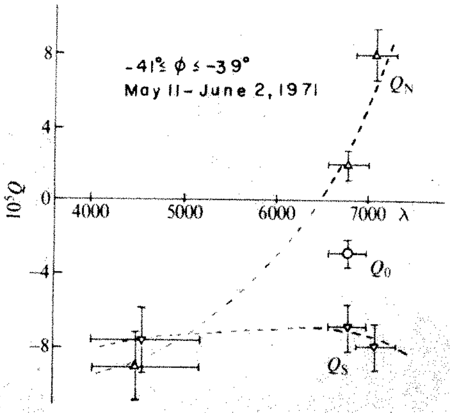

Fig. 3 Crude wavelength dependence of the circular polarization values on Mars. The horizontal error bars are pass bands of the filters used, weighted by the photomultiplier response.

Table 1 Fractional Circular Polarizations in Units of 10^{-5}

	Dates (1971)	Mean φ	Mean λ	Q_0	Q_N	Q_S
Venus	May 20, 23; June 1	$-37°$	6,800	—	$-(7\pm2)$	$+(5\pm1)$
Mercury	June 2	$-67°$	6,800	$+(12\pm4)$	$-(2\pm2)$	$+(18\pm6)$
Moon	May 31	$+90°$	6,800	—	$+(4\pm1)$	$-(3\pm1)$
Uranus	May 23	$+2°$	5,000	(0 ± 1)	—	—
Neptune	June 1	$0°$	5,000	$-(20\pm40)$	—	—

signal averaging over one hour on the 88 inch telescope (Uranus), and about three hours averaging on a 24 inch telescope (Neptune). As far as the polar scattering effect is concerned, if these planets are reasonably symmetric no finite values of Q_0 are expected. It seems feasible to resolve Uranus into north and south halves in a future measurement.

The Moon

The observing scheme in Fig. 1*b* was used to measure Q values on the Moon. Here it was not convenient with the existing polarimeter and telescope optics to make hemisphere measurements. We used an aperture diameter of about 1 arc minute, and selected a sequence of three mirror-image pairs of regions located at complementary northern and southern lunar latitudes of very roughly $\pm45°$, as shown in the sketch. The regions were selected to be as far as possible free of severe relief features. Regions N1 and N3 (and southern counterparts) were near the terminator and the limb respectively, with N2 intermediate. In either hemisphere the Q values for locations 1, 2, and 3 were within a factor of three of each other and had the same sign. The two averages Q_N and Q_S of each of these sets of three values are entered in Table 1; these may reasonably be compared with the hemispheric averages measured on the planets. The phase here was first quarter (half Moon waxing), corresponding to $\varphi = +90°$. The polar values are seen to have the same signs as for Jupiter at positive φ.

Models for the Polarization

The rudimentary model for elliptically polarized scattering at a gaseous surface[2] is consistent with the signs of the polar effect on Jupiter and Venus. What, however, happens with solid surfaces, as on the Moon? Although no theoretical treatment has been given, we may appeal to an extensive laboratory study by Pospergelis[3] of the ellipticity of initially unpolarized light as scattered from a variety of rock and mineral surfaces. For comparison we must point out that our Q equals $-S$ in his notation, where S is the conventional fourth Stokes parameter. His analysis involves certain angles—the phase φ (which has the same meaning as in this article), and the angles γ and ψ giving the orientation of the plane scattering surface. In our context we interpret γ and ψ as the latitude and longitude respectively of a local scattering region on a sphere. (The region on the sphere nearest the observer has $\psi = 0°$.) His results for the circular polarization show, as well as the quite general antisymmetries $Q(-\varphi) = -Q(\varphi)$ and $Q(-\gamma) = -Q(\gamma)$, sign change on variation of φ, not dictated by symmetry considerations. The situation is complicated by the behaviour with respect to ψ; but for scattering from the entire north or south half of the visible surface of a planet at phase φ, there is a mean ψ roughly equal to $\varphi/2$. For $\psi = \varphi/2$, Pospergelis's data for all surfaces investigated (excluding unusual materials with optical activity) indicate that for all φ between 0° and a critical phase φ_c the hemispheric values Q_N and Q_S should have opposite signs from the gas-layer case; $Q(\varphi_c)$ is zero, and for $\varphi > \varphi_c$ the signs agree with those of the gas case. Evidently φ_c depends on the nature of the surface, but the typical value is around 70°. (Another critical value $\varphi \sim 40°$ is mentioned by Pospergelis[3] but that is for $\varphi = 0°$. We have deduced $Q(\varphi)$ for the case $\varphi = \varphi/2$ from families of curves given for a typical surface.) The gas-layer model[2] does not have any such critical angle, $Q(\varphi)$ having one sign over the interval $0° < \varphi < 180°$.

The mechanism for elliptically polarized scattering from condensed matter is different from the gas-layer case. We are considering a model based on double specular reflexions from the facets of crystal grains exposed on a surface. (Equivalently this could be a layer of aerosol particles large compared to a wavelength.) The first reflexion linearly polarizes the ray; the second, from an adjacent grain, elliptically polarizes it by virtue of the material being slightly absorbing. The critical angle φ_c is perhaps related to Brewster's angle for the substance.

The signs of Q_N and Q_S on Mars in the deep red (Fig. 3), at $\varphi = -40°$, are consistent with the conclusions for solid surfaces, for it is fairly clear that the magnitude of φ is less than φ_c. The data for the Moon, at $\varphi = +90°$, are similarly consistent as here we seem to have $\varphi > \varphi_c$. With Mercury the situation is less sure, and little more can be said until investigations at other phases are carried out.

One difference between the data given here and the laboratory results of Pospergelis is in the general magnitudes. His values are of the order 0.1% to 1%, whereas ours are between 0.001% and 0.01%. As noticed empirically[3], the elliptical polarizing power is drastically reduced in a powdered sample as compared to polycrystalline rock. On the face of it this implies that Mars, the Moon and presumably Mercury are largely covered with dust or other fine-textured material, and of course the nature of lunar dust is now well known. The suppression of the polarization is probably because the double reflexion mechanism gives way to multiple reflexions, that is, a ray is trapped in surface cavities before scattering out, randomizing the polarization; or perhaps the particle size becomes smaller than a wavelength and Rayleigh scattering occurs, which cannot produce elliptical polarization by the mechanism described.

What meaning does the polar scattering effect have for astronomy? Given a better knowledge of the origin of the effect, it can give information on planetary surfaces. Even without such knowledge the symmetry aspects alone are of immediate use. A dramatic application should be in the study of asteroids. Here we refer to measurement of Q_0—the integrated effect for the whole body—which is nonvanishing for an asymmetric figure. From Q_0 and its time dependence one can deduce facts about the shape and orientation of the body, complementary to the information furnished by linear polarization and the light curve. Finally, because the effect specifically requires absorption, a spectral curve $Q(\lambda)$ might reveal absorption bands difficult to see otherwise; confusion with absorption bands in the Earth's atmosphere would be almost impossible.

Recognizing the polar scattering phenomenon is necessary before we can search for other causes of circular polarization in light from the planets, such as magnetoreflexion or circular dichroism. The latter is important in the detection of biological molecules. For example, the possibility of Martian plant material having optically active scattering properties comparable to those of green leaves[3] can be tested by searching for the circular dichroism band at 7000 Å. As the circular-dichroic ellipticity neither vanishes nor changes sign at $\varphi = 0°$, such an effect would stand out clearly at opposition. (It happens that our two filter points at 6800 Å and 7100 Å in Fig. 3 approximately straddle that particular band, although they were not selected with such an investigation in mind. The rapid change in Q values between the two wavelengths is likely to be related to the transition from solid-surface to atmospheric scattering, as indicated earlier.) In forthcoming observations a monochromator will be used to study $Q(\lambda)$ with a resolution of about 20 Å on Mars and other planets.

The Evolution of the North-East Atlantic

C. A. WILLIAMS & DAN McKENZIE
Department of Geodesy and Geophysics, Cambridge

Magnetic data taken over a sixteen year period have been analysed and information on the evolution of the North-East Atlantic has been deduced.

It is well known that the evolution of ocean basins can be worked out in considerable detail from magnetic lineations observed at sea level. This technique has already been applied to the Pacific, Indian and South Atlantic oceans, whose evolution is now known in some detail. Very little work has been carried out so far on the North Atlantic, probably because the slow rate of separation of Eurasia and North America has

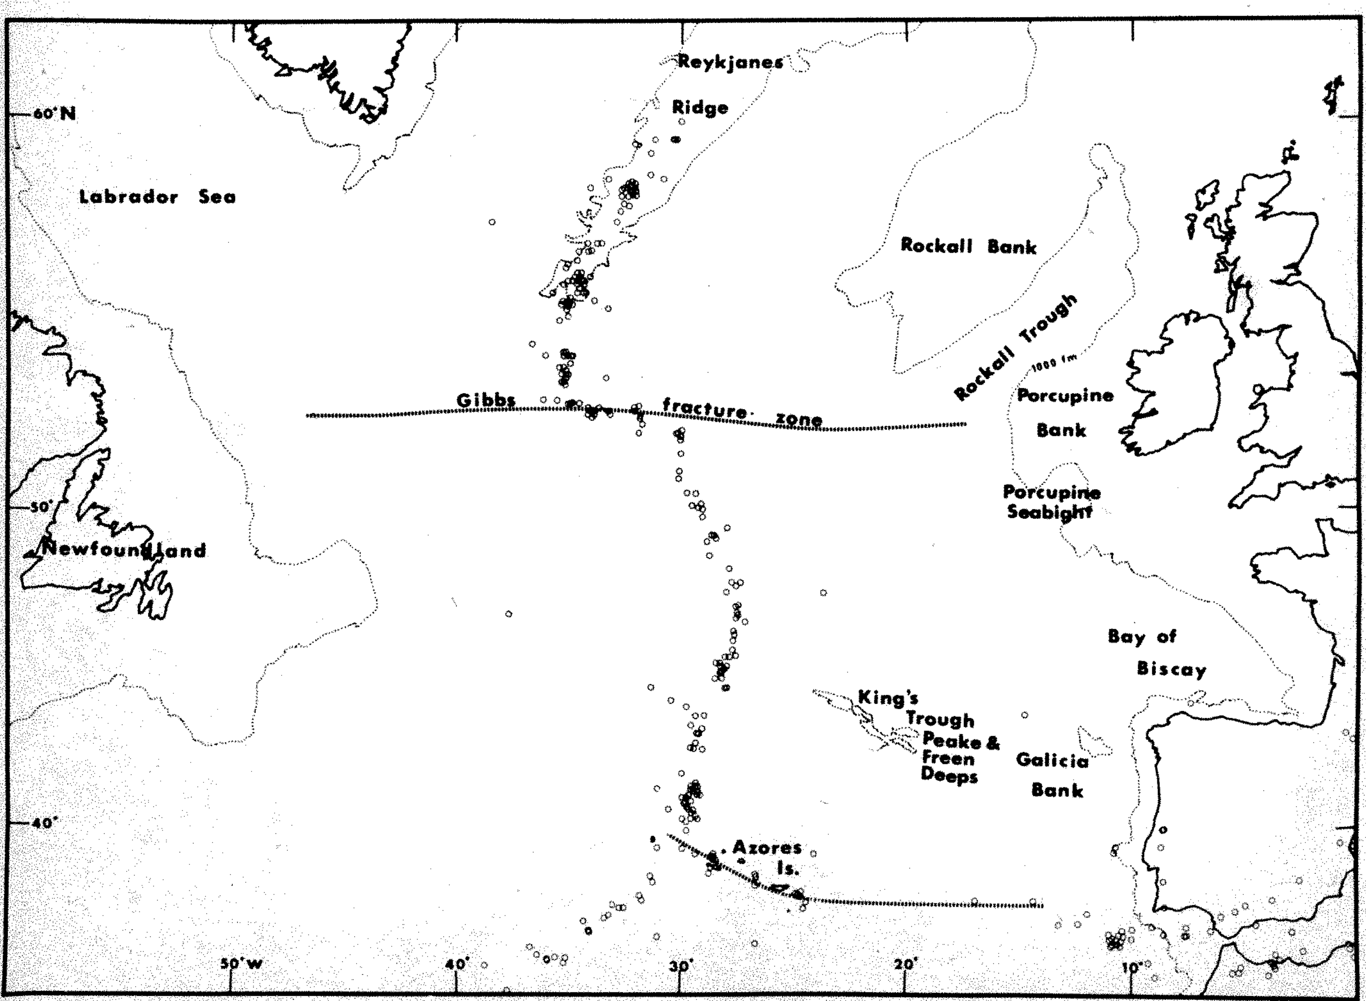

Fig. 1 Location map of the North Atlantic, with USCGS earthquake epicentres.

caused the anomalies to be harder to identify. This is partly because the details of short wavelength anomalies cannot be resolved from the sea surface and also because the seafloor spreading lineations are confused by anomalies from topographic effects and serpentinite intrusions (F. Aumento, personal communication).

Most of our data (Fig. 2) lie within the region bounded by the Azores–Gibraltar Ridge, the Mid-Atlantic Ridge, the Gibbs fracture zone and the continental margin. It is this area with which this article is primarily concerned. It is, however, particularly difficult to apply plate tectonics to a restricted region and our interpretation also depends upon anomalies identified by Pitman and Talwani in the North-West Atlantic[1].

The principal features of the seafloor in this region are the Azores–Gibraltar Ridge, which is seismically active, Kings Trough and Peake and Freen Deeps[2], the Gibbs fracture zone at 53° N and the present ridge crest. The continental margin from southern Spain to 53° N contains four major indentations. The largest of these is the Bay of Biscay. The other three are Porcupine Seabight[3] and Rockall Trough (Fig. 1) and the southern end of Hatton–Rockall Basin[4].

The other major feature on the continental margin is an elongated sediment-filled trough, parallel to the north coast of Spain[5], and characterized by a large negative gravity anomaly. These features must have been formed since the separation of Europe and North America and the evolution of the North Atlantic, recorded by the magnetic lineations, should help to understand their origin.

Magnetic Anomalies

Magnetic measurements have been made in the North-East Atlantic by the Department of Geodesy and Geophysics, Cambridge, since 1956, and wherever possible these original records were used. Other data collected by the British and Dutch Navies[6] and Bedford Institute, Canada (C. A. Williams and D. M. Porteous, account in preparation, and D. I. Ross, Bedford Institute Geophysics report, 1967), were also used, though not in the form of the original records. These magnetic data were digitized and the International Geomagnetic Reference Field[7] removed. The resulting anomaly profiles were plotted at right angles to the ships' tracks on 1 : 1 m scale charts at a scale of 200 γ to 1 inch. The strike of the lineations obtained from these charts was then used and the ship's tracks projected perpendicular to it. The anomalies were identified with the help of synthetic profiles at exactly the same scale and strike. A more detailed description of this procedure can be found elsewhere[8].

The profiles projected at right angles to the strike of the lineations are shown in Figs. 3 and 4 and the lineations themselves in Fig. 6. The synthetic profiles were obtained from the reversal time scale of Heirtzler *et al.*[9] with McKenzie and Sclater's modification of the time scale beyond anomaly 30. A depth to magnetic basement of 3.3 km was assumed from the ridge axis to anomaly 5 and of 5 km beyond anomaly 5. The reduced amplitude of the older part of the synthetic profile is probably due to a palaeolatitude effect since this part of the ridge was then closer to the magnetic equator. Since the lineations change trend in this region the strike of the line perpendicular to them is not constant.

The profiles in Figs. 3 and 4 show that all the anomalies from 1 to 32 are present in this part of the North Atlantic. This conclusion differs from that of Talwani, Pitman and Heirtzler[11] and Pitman, Talwani and Heirtzler[1] who consider that there was a pause or extreme slowing down in spreading between 38 and 9 m.y. ago (anomalies 13–5). Their identification of anomalies at the beginning and end of the sequence agrees with that in Figs. 3 and 4. The main difference between

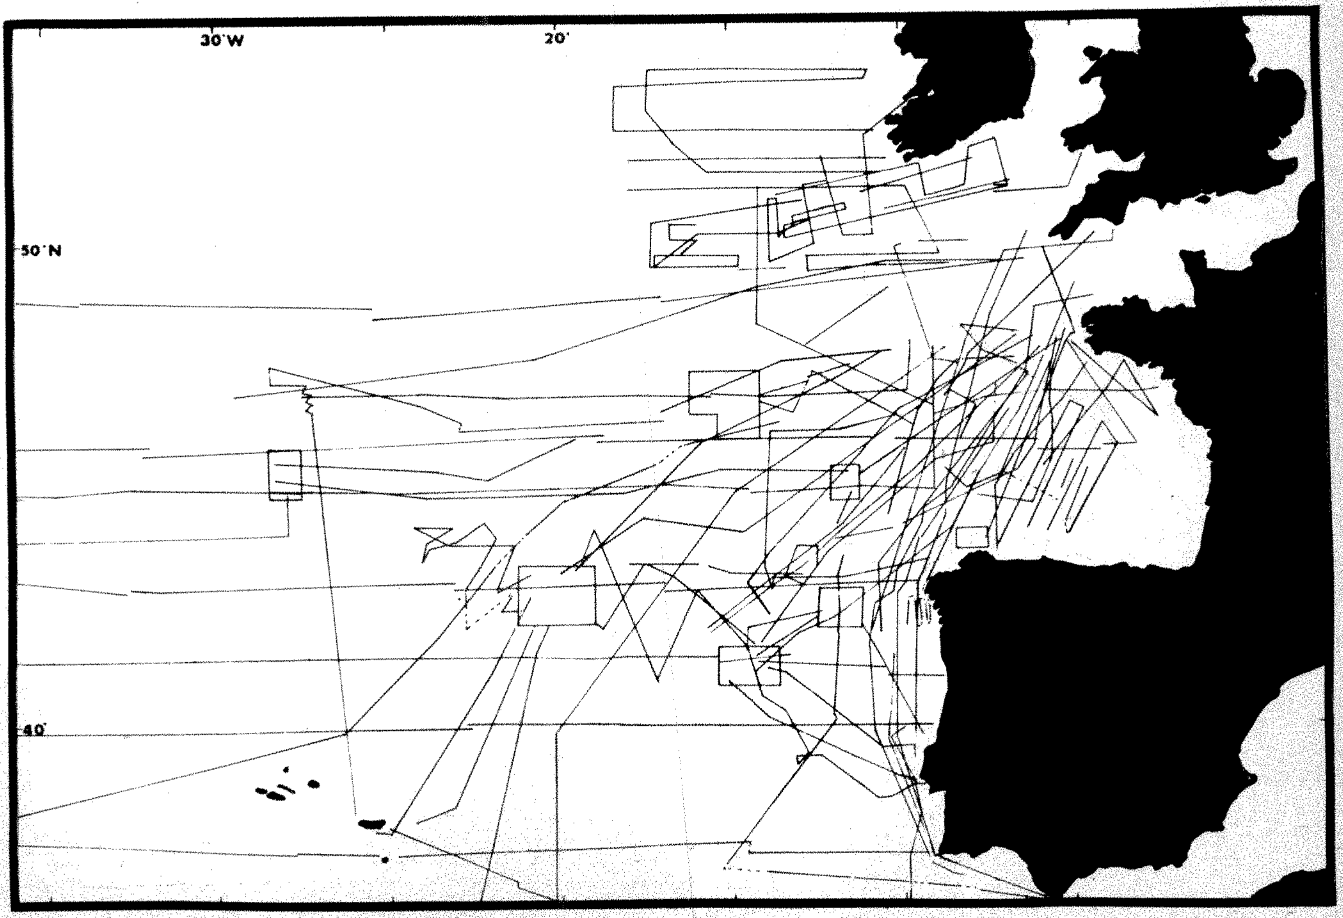

Fig. 2 Ships' tracks along which magnetic data are available. Areas of detailed survey are outlined.

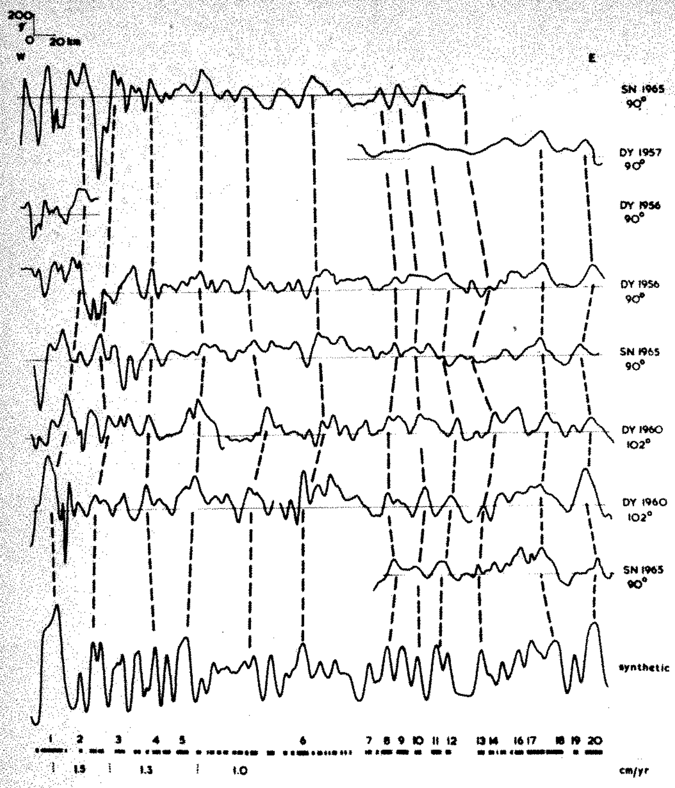

Fig. 3 Projected anomaly profiles from anomaly 1 at the Ridge Crest to anomaly 32. The cruise identification and the directions along which the tracks are projected are shown. The angle is not constant since there is a bend in the lineations in this region. The synthetic profile was calculated after Heirtzler *et al.*[9] and the positively magnetized blocks are numbered according to the convention of Pitman and Heirtzler[10]. The complete sequence of anomalies can be identified. The synthetic profile is calculated at 45° N, except beyond anomaly 24 where a palaeolatitude of 25° N was used. Cruise identifications: Dy, RRS Discovery; Sn, H. Neth, M. S. Snellius 1965 project NAVADO lines J to N; H, CSS Hudson; JM, RRS John Murray; B, CSS Baffin.

these two interpretations depends upon which anomaly is identified as anomaly 13. Fig. 5 shows the two interpretations of this crucial section together with the projected profiles on which the anomalies are most easily recognized. Pitman and Talwani believe 13 to be an anomaly closer to the ridge crest than the one we have identified.

The reversal time scale is not yet known beyond anomaly 32 (79 m.y.). Immediately preceding this there is thought to have been a period of approximately 50 m.y. with no reversals[12]. Seafloor formed during this period is known as the quiet zone in the Pacific. The seafloor east of anomaly 32, where no lineations are observed, was probably formed at this time. It is, however, important to point out that there are other explanations for the absence of magnetic anomalies since lineations are easily destroyed.

On the eastern side of the mid Atlantic Ridge there are two regions where anomalies are found which are not part of the numbered sequence formed since the Upper Cretaceous (Fig. 6). The first region is the Bay of Biscay where a pattern of magnetic lineations fanning from the South East corner of Biscay have been mapped by Matthews and Williams[13]. The strike of these lineations fanning from the south-east corner of Biscay have northern Biscay they appear to be truncated by part of the quiet zone to the east of anomaly 32, suggesting that the Biscay sequence is older than anomaly 32[14]. As there is evidence of reversals here, the seafloor appears to be more than 50 m.y. older than anomaly 32, that is older than 125 m.y. which is lower Cretaceous.

The second region where older anomalies occur is off South-West Spain, where a group of lineations have approximately north–south strikes and fan out in a similar way to those of Biscay (Fig. 6). One of these anomalies is anomaly J and has also been identified on the western side of the Ridge[1].

Evolution of the North-East Atlantic

The south of the North Atlantic began to open in the Late Trias with the separation of North America and Africa[1]. In pre-upper Cretaceous times the spreading ridge extended northwards into Biscay. The fanning of the Biscay anomalies and also those off South-West Spain suggests that both sets were formed synchronously accompanied by the anticlockwise

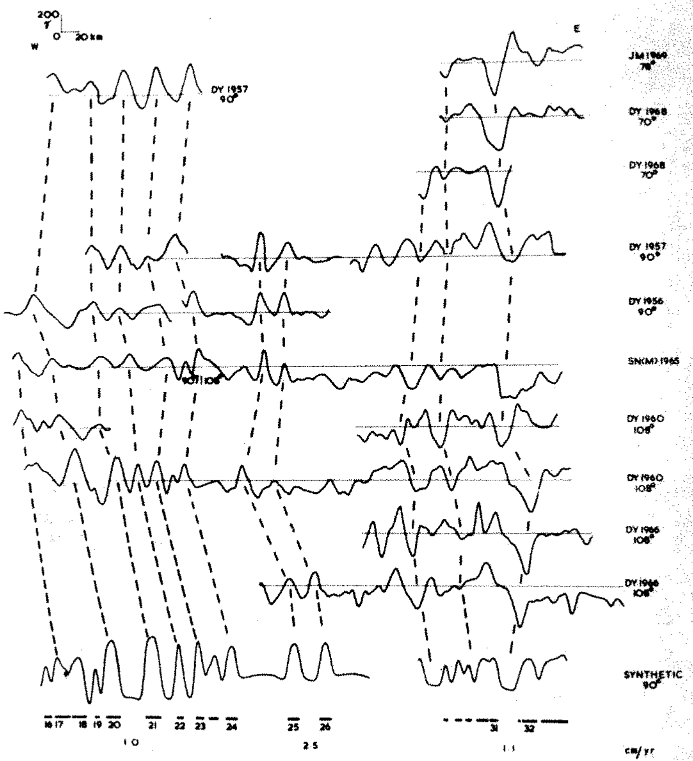

Fig. 4 See caption to Fig. 3.

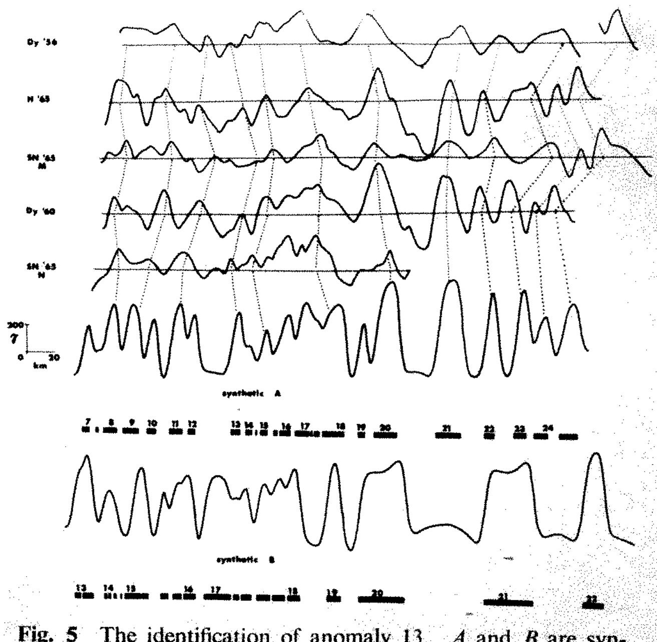

Fig. 5 The identification of anomaly 13. *A* and *B* are synthetic profiles. *A* according to this interpretation with a spreading rate of 1 cm yr^{-1} and *B* according to Pitman and Talwani with a spreading rate of 2 cm yr^{-1} for comparison. Anomalies 24 to 20 are easily recognized and the decrease in spreading rate can be seen across anomaly 24 and in Fig. 4. Cruise identifications as for Fig. 3.

motion of Iberia. If this suggestion is correct, then one of the Biscay anomalies is anomaly J. It seems likely that the Bay of Biscay was formed by the rotation of Spain in the Upper Jurassic or Lower Cretaceous.

By the time of anomaly 32, Biscay had ceased to be active and the spreading ridge extended north-westward to the north of Biscay (Fig. 7). The motion at the northern end was probably taken up by the Gibbs Fracture Zone. By the time of anomaly 31 the ridge extended beyond the fracture zone into the Labrador Sea[15]. The northern part of anomaly 32 is sub-parallel to the continental shelf edge and crosses the mouth of Porcupine seabight. This feature was therefore probably formed before anomaly 32 during the early phases of separation of Europe and North America. The seabight, Rockall Trough and Hatton–Rockall basin are likely to have been formed by the ridge attempting to extend by breaking through the plate to the north. This does not necessarily imply that these are floored by oceanic crust, however, as they may have been produced solely by extension of continental crust.

Anomaly 32 is less easy to identify than the negative anomaly

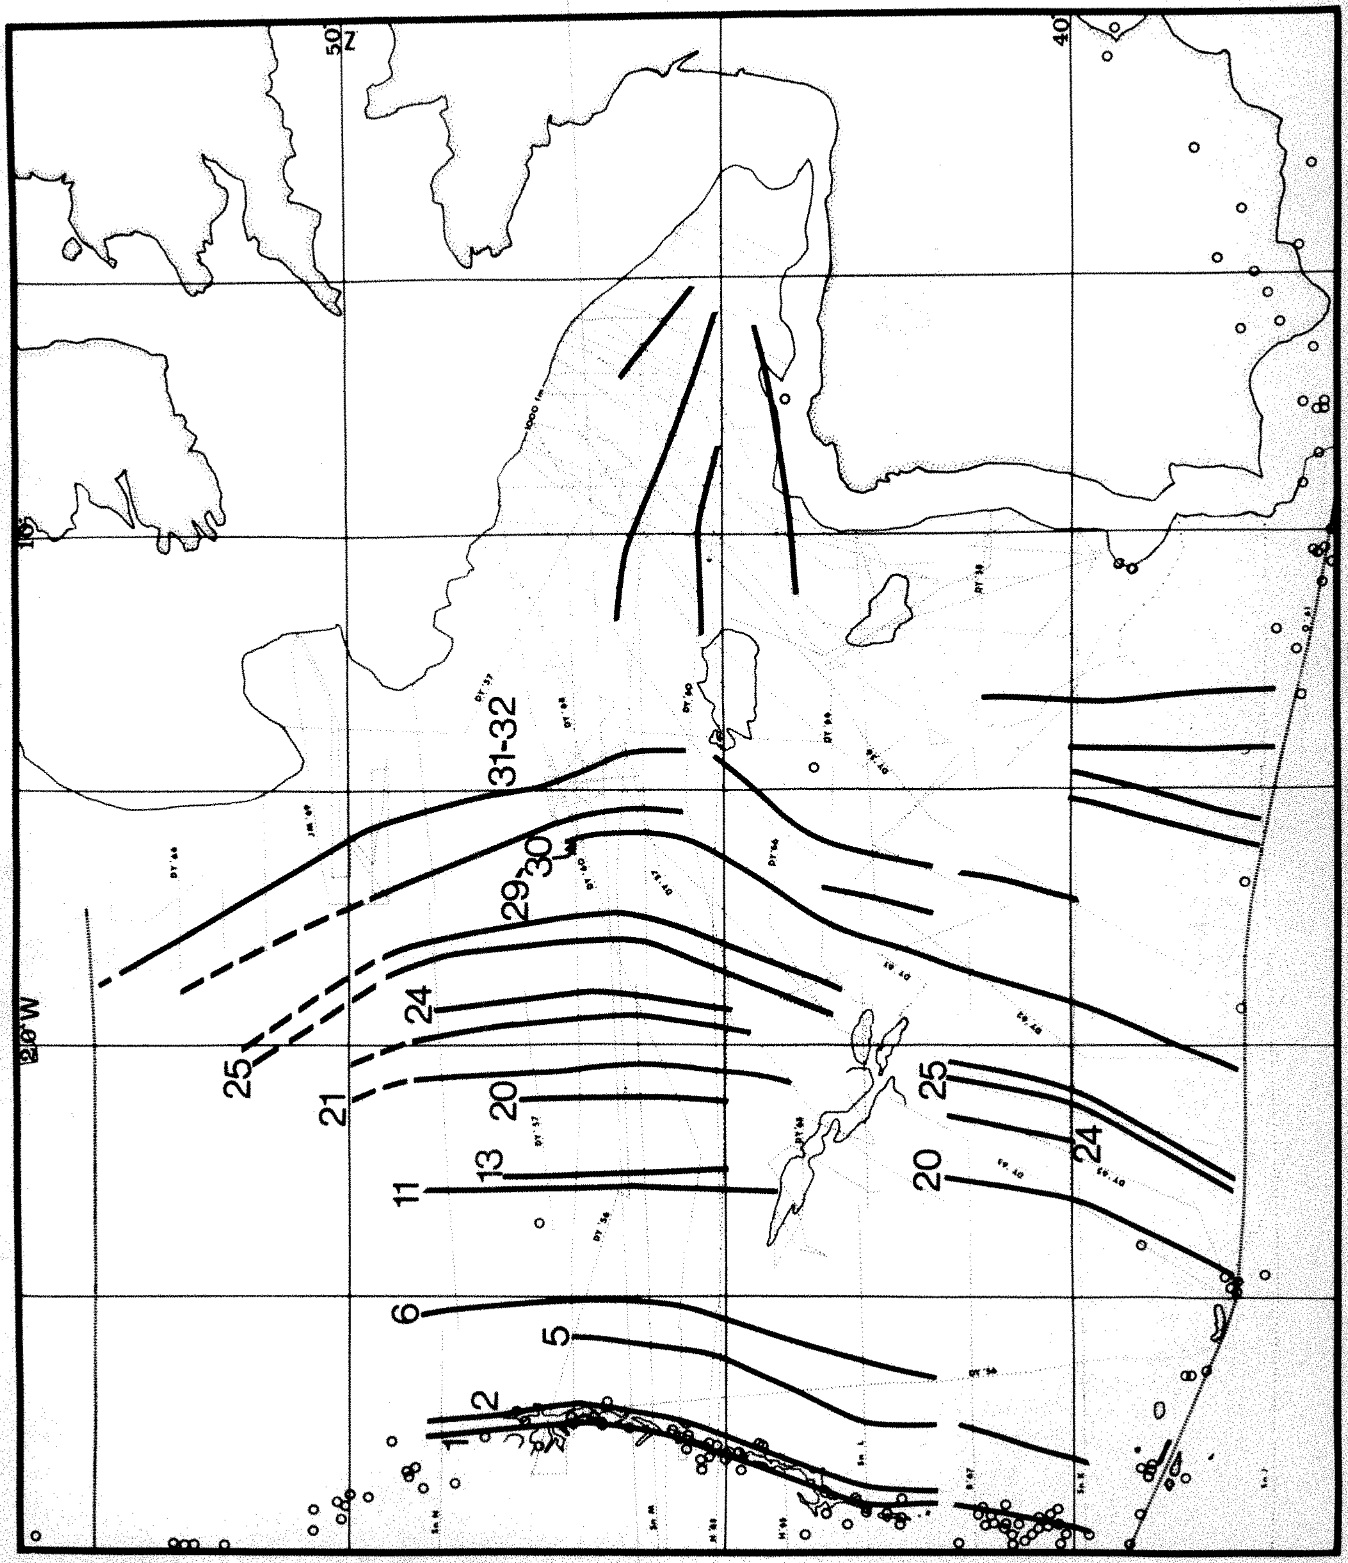

Fig. 6 Magnetic lineations. Only the most prominent ones are shown; the ships' tracks are dotted and indicate the control on the lineations. Cruise identifications as for Fig. 3.

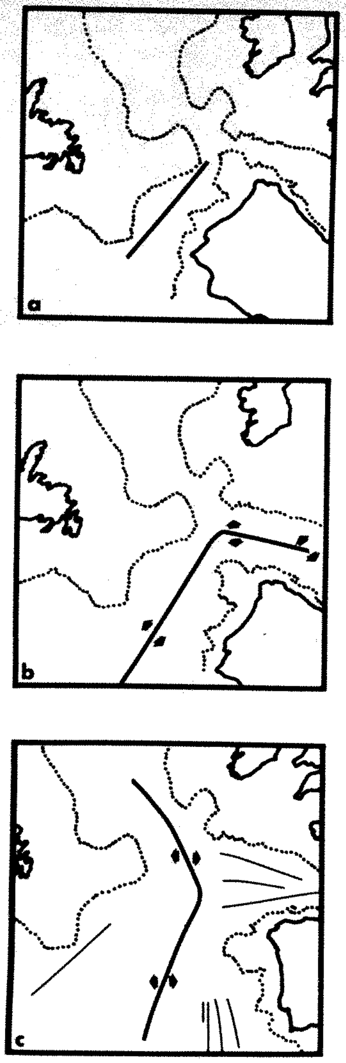

Fig. 7 Diagrammatic reconstruction of early opening of Biscay and the North Atlantic. The thick line represents the Median valley. *a*, Early Mesozoic extension between Iberia and Newfoundland; *b*, extension of the spreading centre into Biscay; *c*, extension north of Biscay about 80 m.y. BP (anomaly 32).

between 31 and 32 (Figs. 4 and 6), which forms a striking feature on most profiles. The 31–32 lineations have a north-easterly trend south of Biscay, which changes off the mouth of Biscay and becomes north-westerly. The adjacent younger lineations also show this changing trend. Similar anomalies have been found in the North-East Pacific, where the lineations forming the Great Magnetic Bight have two straight segments meeting at an angle. Unlike the North Pacific anomalies, however, the eastern north Atlantic lineations young in the concave direction. They are therefore difficult to explain by the evolution of a triple junction similar to the Great Magnetic Bight. Moreover, Pitman *et al.*[1] have identified similar shaped lineations on the opposite side of the Atlantic. If the bend in the lineations on both sides of the ridge is fitted together, the motion required to do so is essentially parallel to the Gibbs fracture zone, and therefore the ridge must have been spreading obliquely to the lineations at this time.

This curious geometry is not easily explained, because if a ridge spreads symmetrically it cannot change its shape. Two possible mechanisms which would account for the observations are that spreading was asymmetric or that the ridge jumped, forming several small offsets. These two possibilities and their consequence are illustrated in Fig. 8. The present density of ship tracks is not sufficient to choose between the two mechanisms, and if there are indeed small fracture zones present in this area the strike of the lineations in Fig. 6 will not be correct. It should be straightforward to do this by a detailed survey, especially if satellite navigation is available. Anomalies west of 31 are presumably 29 to 27, but cannot be numbered with any certainty. Anomalies 25 and 26 are, however, easily recognized on most tracks. Though these lineations are sub-parallel to anomaly 31, careful measurement of their strikes shows that the ridge has become straighter with time. This process continued until anomaly 24, and after anomaly 23 the lineations are straighter on both sides of the Atlantic. These events are closely related in time to the extension of the ridge to the north-east to form a triple junction south of Greenland[16] at anomaly 24 time. There is also a slight change in trend of the lineations in Fig. 6 at anomaly 18 time, which is the time at which the spreading ceased in the Labrador Sea.

The approximate spreading half-rates were 1.1 cm yr^{-1} at anomaly 32 time, between anomalies 26 to 24 spreading increased to 2.5 cm yr^{-1} and slowed to 1 cm yr^{-1} at anomaly 23. Spreading continued at 1 cm yr^{-1} until anomaly 6 when it increased to 1.3 cm yr^{-1}. At anomaly 5 it increased again to the present rate of 1.5 cm yr^{-1}.

Bacon and Gray[17] have suggested that Spain moved eastward relative to Europe after the Bay of Biscay opened. The magnetic anomalies in Fig. 6 do not permit a large strike-slip motion after anomaly 32 was formed, and therefore any such motion must have occurred before the Upper Cretaceous. The most likely explanation for the sedimentary trough north of Spain is that it was produced by a small amount of crustal consumption along this boundary, perhaps during the Eocene when the Pyrenees were folded.

Fig. 6 also shows that there is no major horizontal displacement across Kings Trough and Peake and Freen Deeps. Therefore these features are not the relics of a large transform fault. They cut anomalies from 24 to the first part of 6 and may well be connected with the elimination of the bend in the ridge axis at anomaly 24 time and subsequent small changes in ridge orientation which took place during the period of anomalies 24 to 6.

This study of the magnetic lineations shows that the formation of the North-East Atlantic began with the separation of Spain from North America and Europe in probably the Upper Jurassic and early Cretaceous. The ridge extended northwards as far as the Gibbs fracture zone at 53° N by the Upper Cretaceous and beyond this into the Labrador Sea by anomaly 31 time. Most of the complications of the European continental margin and surrounding seafloor appear to be the result of this intermittent northward extension of the mid-Atlantic Ridge into Biscay, possibly beginning to extend into Porcupine

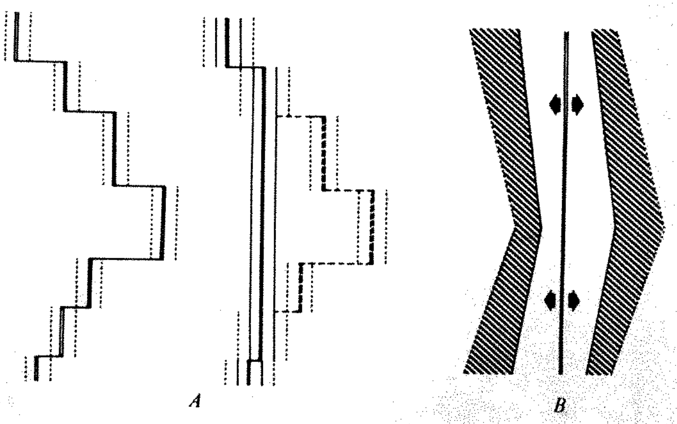

Fig. 8 Two possible mechanisms to account for the shape of the observed lineations. *A*, The ridge straightens by reducing the number of offsets. *B*, Spreading is asymmetric across certain segments of the ridge. This has not been conclusively shown to occur.

seabight, Rockall Trough and Hatton–Rockall basin. Sometimes these extensions were long term and sometimes very temporary. This behaviour is strikingly similar to that of the ridge in the Indian Ocean[8].

We thank Mrs Annette Fahlman and Mrs Alette Lawson who digitized these data and ran all the programs. We also thank the late Dr M. N. Hill and Dr D. H. Matthews under whose guidance the data have been collected and the officers, crew and scientists on board the ships who took part in the data collection. This work was sponsored by the Natural Environment Research Council.

Establishment of Symbiosis between *Rhizobium* and Plant Cells *in vitro*

R. D. HOLSTEN, R. C. BURNS, R. W. F. HARDY & R. R. HEBERT

Central Research Department, E. I. du Pont de Nemours and Company, Wilmington, Delaware 19898

A symbiotic nitrogen-fixing relationship has been established in culture between soybean cells and the bacterium *Rhizobium*.

SYMBIOTIC fixation of atmospheric nitrogen by leguminous plants is perhaps the most quantitatively important agency by which this element is incorporated into the biosphere, and is the principal process for maintaining nitrogen fertility in agriculture. The interaction of plants of the family Leguminoseae and specific bacteria of the genus *Rhizobium* in this symbiotic relationship is not yet well understood, probably because of the absence of a suitable defined experimental system. Other workers have used isolated plant roots in combination with the appropriate bacteria[1–4], and, more recently, plant cell and tissue culture[5]. Although stimulation of plant cell differentiation and lignification apparently resulted, no evidence for intercellular bacterial symbiosis could be found.

We have attempted to establish a symbiotic N_2-fixing relationship with plant cells and microorganisms *in vitro*, using the techniques of aseptic plant cell culture in conjunction with the sensitive acetylene–ethylene assay for nitrogenase activity. We consider that such a system can be used further to elucidate the factors which control nodulation processes and N_2-fixing activity *in vivo*.

Soybean Root Cell Cultures

Seeds of soybean (*Glycine max* var. Acme) were surface sterilized by immersion in a commercial hypochlorite solution ('Zonite', Chemway Corp., Wayne, New Jersey) for 15 min, and rinsed with sterile distilled water. Seed was placed on the surface of an agar (1% w/v) solidified medium composed of the mineral salts (MS medium)[6] supplemented with sucrose, 30 g/l., for germination in the dark at 26° ± 1° C. All media were sterilized by autoclaving at 121° C for 15 min.

When the primary root was approximately 4 cm long, it was excised aseptically, and a 5 mm explant was removed 2.5 cm behind the growing tip. This explant of root origin was placed on the surface of 50 ml. of agar-solidified MS medium supplemented with 15% whole coconut milk (CM, Grand Island Biological Co.) and 2 mg/l. 2,4-dichlorophenoxyacetic acid (2,4-D) contained in a cotton stoppered 250 ml. Erlenmeyer flask. The medium was adjusted to *p*H 6.0 before autoclaving. The explanted root section was incubated at 26 ± 1° C in the dark.

An actively growing mass of undifferentiated cells (callus) was produced on the root explant in 10–14 days. The callus was then aseptically removed and portions subcultured to fresh MS medium supplemented with 15% CM and 2 mg/l. 2,4-D. In these and subsequent subcultures, we used a liquid medium similar to that described, with 225 ml. of medium in a modified 1,000 ml. flask (Blaessig Glass Co., Rochester, New York)[7], as well as 50 ml. agar-solidified medium in 250 ml. Erlenmeyer flasks. The liquid cultures were incubated on a klinostat rotating at 1 r.p.m.[8] in the dark at 26 ± 1° C. An actively

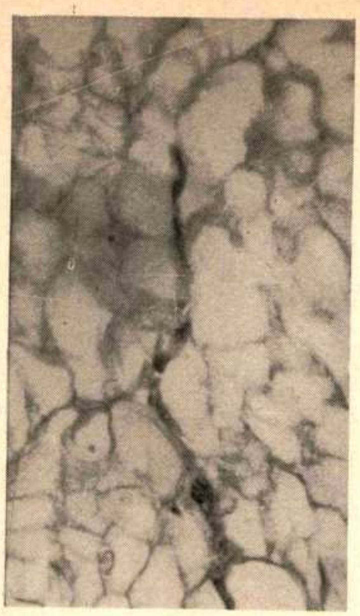

Fig. 1 Paraffin section of a callus culture showing *Rhizobium japonicum* penetration through an infection thread-like structure (× 600).

growing cell and callus population with a cell doubling time of the order of 18 h was established in the liquid environment over a 14–21 day period. Subculture of the liquid system was carried out at 20–30 day intervals to maintain an actively dividing cell population. Cotyledonary tissue was similarly treated to establish cell cultures from this source.

Bacterial Growth

Rhizobium japonicum strains 61A76 (supplied by Dr Joe C. Burton of the Nitragin Co., Milwaukee, Wisconsin) and ATCC 10324 were grown in a liquid culture medium composed of (in g/l.): K_2HPO_4, 1.0; KH_2PO_4, 1.0; $FeCl_3 \cdot 6H_2O$, 0.005; $MgSO_4 \cdot 7H_2O$, 0.36; $CaSO_4 \cdot 2H_2O$, 0.17; KNO_3, 0.70; yeast extract, 1.0; mannitol, 3.0. The medium was adjusted to *p*H 6.4 before autoclaving at 121° C for 15 min. A bacterial inoculum was added to 40 ml. portions of the above medium contained in 125 ml. Erlenmeyer flasks and incubated at $30 \pm 1°$ C with constant shaking. Subcultures of the bacterial cultures were carried out at 7 day intervals to maintain vigorous stocks. At regular intervals aliquots of the *R. japonicum* cultures were examined microscopically and checked for nodulating activity by application to seedlings of Acme or Kent variety soybeans maintained in a Sherer–Gilette CEL 255–6 growth chamber under a 16 h photoperiod.

Establishment of a Symbiotic Relationship

A large culture flask from the klinostat containing 225 ml. of MS medium with 15% CM, 2 mg/l. 2,4-D and containing an actively growing root cell and callus population of approximately 15 g fresh weight was inoculated with 0.1 ml. (260×10^6 cells/ml.) of a liquid suspension culture of actively dividing *R. japonicum* and returned to the klinostat for incubation. After 3–7 days of incubation, the flask contents were poured through sterile cheesecloth. Plant cells and callus pieces retained on the cheesecloth (designated stage 1) were washed with 250 ml. of sterile MS medium, transferred to fresh growth media of varying composition, and incubated in the conditions described. Concomitantly, portions of the cell population inoculated with bacteria, as well as control tissue without bacteria, were assayed for nitrogenase activity using the acetylene–ethylene assay procedure[9]. Dry weight determinations were performed after drying the tissue for 48 h at 60° C.

Cytological Examination of Tissue

Random samples of the soybean root cell cultures from bacteria-inoculated and control flasks were prepared for paraffin sectioning by fixing in formalin : acetic acid : ethanol (5 : 5 : 90 v/v) or in Fleming's osmic acid fixative for 24 h at room temperature. The tissues were then dehydrated through the ethanol series before being embedded in 'Paraplast' (Mh 56°–57° C) for sectioning. Sections were cut at 8–10 µm, stained with safranin-fast green or Van Gieson's Nile blue and examined with a Zeiss microscope fitted with phase contrast optics.

At the same time similar cell samples were overlaid with 5% glutaraldehyde in Millonig's phosphate buffer (*p*H 7.2–7.4) and fixed for 60 min at room temperature. The fixed samples were rinsed for 20 min, post fixed for 60 min at room temperature with 1% OsO_4, washed with phosphate buffer for 20 min, and dehydrated through an ethanol series up to 100% propylene oxide. The samples were then embedded in 'Epon 812', polymerized at 60° C for 24 h, and sectioned at 500 Å using a diamond knife. The resulting sections were stained with uranyl acetate followed by Karnowsky's lead and examined in an RCA EMU-3G electron microscope.

Invasion of Cultured Root Cells

Examination of paraffin sections prepared at the time the bacteria-inoculated liquid plant cell cultures were transferred to fresh growth media (stage 1, day 3–7) revealed the presence of structures resembling the infection threads found in *in vivo* nodulating soybean root systems. These "pseudo-infection threads" of the *in vitro* system were observed to penetrate the undifferentiated cell mass for a considerable distance before entering the cell cytoplasm (Fig. 1). *Rhizobia* were observed within the thread-like structures as they traversed the intercellular spaces within the cell mass. Whenever *Rhizobia* entered a plant cell from the terminus of a "pseudo-infection thread", they multiplied to displace the plant cell contents completely with bacteria (Fig. 2). No other morphologically differentiated cells (for example conducting elements) were found in any of the

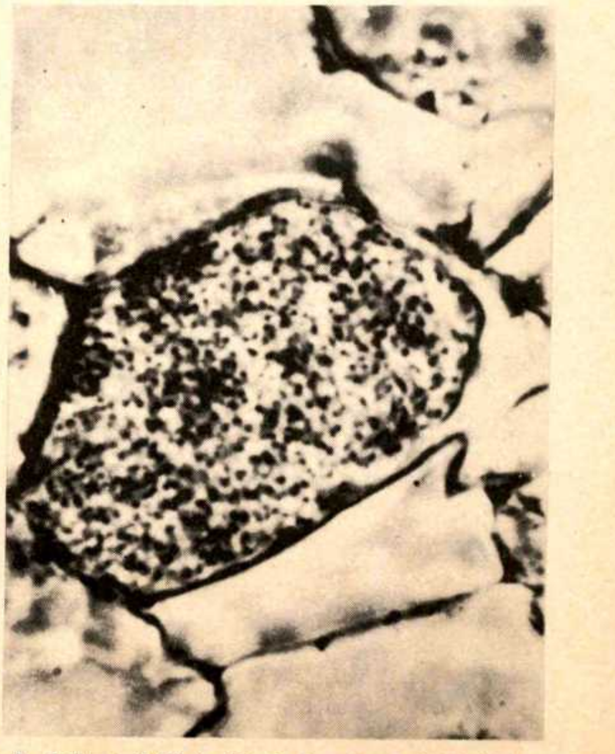

Fig. 2 Callus cell filled with *R. japonicum* after initial penetration.

bacterially populated plant cell masses at this developmental stage.

Continued Development of the Symbiotic System

Following the initial penetration of the plant cells by *Rhizobia* (3–7 days after bacterial inoculation of the cell culture flask), the cell cultures were transferred to fresh media, both liquid and agar-solidified, for development of stage 2. The following media were utilized: (1) MS, (2) MS plus 10–15% whole CM and (3) MS plus 10–15% whole CM and 2 mg/l. 2,4-D. Control cultures of soybean root cells (without bacteria) were transferred to similar media and incubated in the same conditions. All cultures were incubated for 7–20 days after transfer before being examined for bacterial penetration and for nitrogenase activity. Light-grown cultures received approximately 500 foot-candles of light from Duro-Test Optima lamps (Duro-Test Corp., North Bergen, New Jersey).

Fig. 3 shows that the degree of rhizobial invasion after transfer of the cultured soybean root cells is related to the growth factor additions to the MS medium. Most extensive invasion is found after transfer of bacterially populated plant cells to MS medium containing no exogenous growth supplements (Fig. 3*a*). With the addition of whole CM (Fig. 3*b*) and the combination of CM and 2,4-D (Fig. 3*c*) the number of cells inhabited by the *Rhizobia* is markedly reduced. Assays for nitrogenase activity under each of the tested culture conditions (Tables 1 and 2) show this activity to vary directly with the degree of bacterial invasion (Table 1). The tissue without rhizobial involvement shows little acetylene–ethylene reducing activity (Table 1) in these assays[11,12]. Table 2 shows that although there is wide variation in the response of individual Acme soybean root cell cultures to *R. japonicum* strain 61A76, there is a definite symbiotic relationship capable of fixing N_2 established in liquid systems, as measured by the acetylene–ethylene technique. Attempts to establish an active symbiotic relationship using Kent variety soybean root cells in liquid culture have been less successful. Even with Acme variety soybeans, the use of a different strain of *R. japonicum* (ATCC 10324) resulted in a lower over-all nitrogenase activity although electron microscopy showed bacterial penetration of the cultured cells. Cotyledonary tissue has shown no propensity to establish a symbiotic association in the conditions of this study.

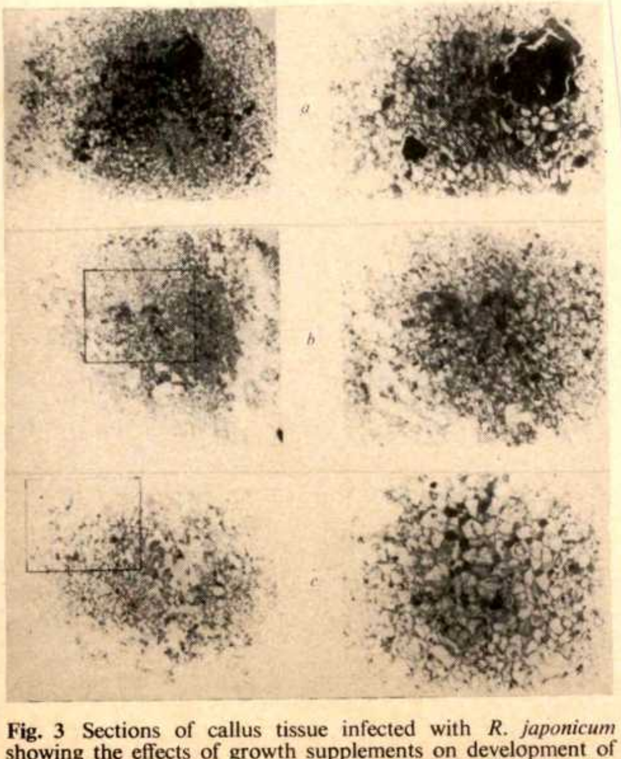

Fig. 3 Sections of callus tissue infected with *R. japonicum* showing the effects of growth supplements on development of the symbiotic association. See text for details of treatments. Left, × 350; right, × 700.

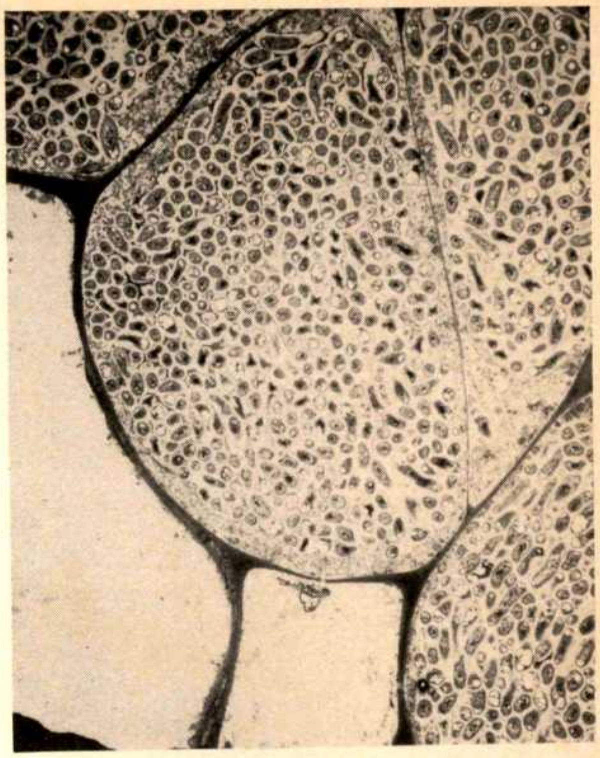

Fig. 4 Electron micrograph of cultured soybean callus infected with *R. japonicum* (× 4,160).

Table 1 Acetylene to Ethylene Reduction by Soybean Root Cell Cultures inoculated with *Rhizobium japonicum* Strain 61A76

	nmol C_2H_4/g fresh weight × 24 h	
	Light	Dark
MS	72.8	318.6
MS+10% CM	36.6	129.0
MS+10% CM+2 p.p.m. 2,4-D	7.7	37.9
Uninoculated control MS+10% CM+2 p.p.m. 2,4-D	0.4	2.1

The assay was carried out 21 days after initial bacterial inoculation and after transfer to semi-solid agar medium for 14 days. Incubation was under continuous light or dark conditions following initial establishment of symbiosis.

Table 2 Acetylene to Ethylene Reduction by Two Separate Soybean Root Cell Cultures containing *R. japonicum* Strain 61A76 in Symbiotic Relationship

	nmol C_2H_4/g dry weight × 24 h	
	1	2
Tissue +61A76 bacteria	638	88.0
Uninoculated control	307	25.7

Assays were made 3–5 days after addition of the microorganisms to liquid culture.

Electron Microscopic Examination of Symbiotic Cultures

Examination of *Rhizobium*-plant cell cultures with the electron microscope confirmed that *Rhizobia* have entered the cultured plant cells and displaced the normal cytoplasmic components (Fig. 4). In some cases the *Rhizobia* were enclosed within a vesicle which is morphologically analogous to the vesicles found in nodules obtained from whole soybean root systems (Fig. 5). It was further observed that the *Rhizobia* within the cultured root cells contained an inclusion which was similar in appearance to an inclusion of whole soybean nodule bacterioids designated as a polymer of β-hydroxybutyrate. This inclusion became more prominent with increasing time of incubation of the synthetic symbiotic system (up to 15–20 days after transfer). Microscopic examinations of uninoculated tissue showed that there were no microorganismal contaminants present. The media used for maintenance of the plant cell cultures were also found to be devoid of microorganisms and N_2-fixing activity; the bacterial inoculum contained only *Rhizobia* and exhibited no N_2-fixing activity. Thus it is clear that free-living N_2-fixing bacteria are not responsible for our observations.

Functionality of the Symbiotic Relationship

The functional system we have described provides a new tool for the elucidation of the mechanisms controlling nodulation and subsequent N_2-fixation in symbiotic associations.

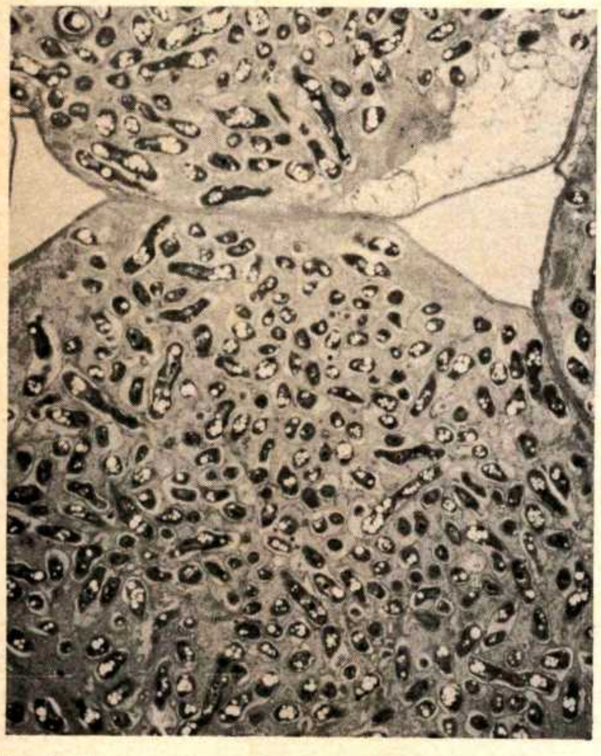

Fig. 5 Electron micrograph of a soybean root nodule infected with *R. japonicum* showing accumulation of β-hydroxybutyrate (×4,160).

The morphology of symbiosis *in vitro* is analogous to that of intact soybean root nodules[13,14]. *Rhizobia* within the cytoplasm of the cultured cells, as in root nodules, are at times enclosed within a vesicle. The intracellular bacteria (bacterioids?) are shown to contain an inclusion which has been tentatively identified as poly-β-hydroxybutyrate[15]. A structure similar in appearance to the infection thread of nodulating systems *in vivo* has been observed in the early stages of bacterial penetration of the cultured plant cells in the liquid milieu. This apparent mode of rhizobial entry into the cultured cells and the subsequent multiplication of the intracellular microorganisms to displace completely the cell cytoplasm are again analogous to processes which are known to occur *in vivo*.

It has further been found that following initial bacterial penetration of the cultured cells, depletion of exogenous supplies of plant growth factors (cytokinins and auxins) in the environment leads to increased cellular penetration by the microorganisms and greater nitrogenase induction. This suggests that the symbiosis, once initiated, is self-sufficient and that any exogenous additions tend to suppress its normal development and function. This agrees with the proposed roles of plant growth regulators in the establishment and maintenance of nodulated symbiotic systems *in vivo*[16,17]. Thus it may be possible to control the process of effective nodulation with factors which alter the levels of endogenous plant growth regulators such as auxins during the critical phases of invasion.

The reduction of acetylene to ethylene as a measure of nitrogenase activity shows that the N_2-fixing potential of the symbiosis increases with the proportion of cellular invasion by microorganisms, and the addition of plant growth factors depresses nitrogenase activity as well as the development of the symbiotic morphology. It should therefore be possible to increase the overall N_2-fixing activity of the system by regulating the degree of cell penetration and subsequent nitrogenase induction through chemical means.

Light does not seem to stimulate the symbiosis *in vitro* once it has been established; but cells grown in the light resisted rhizobial challenge, and no working symbiosis could be established in these cultures. It is possible that cells grown in the light develop a natural defence mechanism against invasion by microorganisms *in vitro*, perhaps through the phytochrome system[18].

The acetylene to ethylene reducing activities (and nitrogenase activity by analogy) achieved so far in the *in vitro* symbiotic system are of the order of 1% of those found in soybean nodules. Microscopic examinations of the symbiotic cell masses in culture showed that only 1–10% of the total cell population was infected with intracellular microorganisms. The activity per cell may therefore be comparable with that found in whole root nodules where more than 90% of the cells appear to contain bacteria. It is also pertinent (Fig. 3) that infection occurs only in the subsurface cells of the callus where physiological conditions might be expected to simulate more closely the cortex of intact roots. The initial infection of the tissue culture occurs through a modification of a peripheral cell of the callus mass and not through a root hair cell as in intact roots. This suggests that symbiosis *in vivo* might also be expected to occur through penetration of epidermal cells other than root hairs in suitable conditions.

We thank Mrs Mary Ann Mattson and Mr M. L. Van Kavelaar for technical assistance.

Search for Isolated Radio Pulses from the Galactic Centre at 151.5 MHz

WE have extended our previous work[1] and searched specifically for pulses from the galactic centre (GC), which might be correlated with the events reported by Weber[2,3]. To discriminate against local interference we looked for pulses received simultaneously by widely spaced receivers; although our results are negative, they allow upper limits to be placed on the radio energy emitted in pulses from the GC.

Table 1 Galactic Centre Data

	Two-fold		Three-fold		Four-fold		Five-fold	
	No. of events	Hours	No. of events	Hours	No. of events	Hours	No. of events	Hours
All stations	187	636	4	368	0	209	0	78
CGH	85	512	1	117				
DGM	41	269	0	111				

Four groups have participated, with receivers at Cambridge, Dublin, Glasgow and Harwell, and a receiver in Malta (at 15.5° E, 36° N) has been operated by the Dublin group. The Malta site is 2,450 km from Cambridge, the nearest of the other sites. Each of the stations was equipped with two directional antennas connected as a phase-switched interferometer of spacing 5λ east–west. The antennas were near-vertical ladder arrays of 6 to 8 half-wave dipoles over reflecting screens, providing beams extending about 15° in elevation and directed towards the GC at transit. Our latitudes (51° to 56° N for the UK and Dublin sites) are far from ideal because the GC is visible for only about 6 h and rises to a maximum elevation of 9°. All stations operated at frequencies close to 151 MHz with bandwidths between 0.2 and 1.0 MHz. Cambridge and Glasgow had each a pair of receivers tuned to frequencies 1 MHz apart to measure dispersion and discriminate against interference. The outputs, with integration times between 0.3 and 3.5 s, were recorded on paper charts at speeds between 6 and 24 inch h^{-1}. The observing period was from May 1 to August 16, 1970, that is, when the GC was in transit during the night—and the analysis was restricted to times when the Sun was below the local horizons.

We found many more pulses satisfying the criterion that the amplitude should be at least 3 times peak to peak noise, than in the earlier observations[1]. Most of these could be attributed to increased interference arising from the high sensitivity of the antennas at low elevations, and also to the fact that the observations were carried out in the summer when atmospheric disturbances are more prevalent.

As before, the records of the individual sites were scanned for pulses which arrived in "coincidence" (that is, within any 2 min period) at two or more of the five sites. Some two-fold and three-fold coincidences were found, but there were no four-fold or five-fold coincidences. The number of coincident events is shown in Table 1 together with the length of time for which such events were possible. The data in Table 1 are restricted to times when the galactic centre was in the beam of the aerials. Data, however, were taken all through the night at some stations, and an analysis of these is shown in Table 2, together with the results of a "random" test in which the times of events were shifted by an arbitrary time relative to each other. From this test we conclude that the real two-fold rates are not significantly greater than the random expectation and we set a three-fold coincident rate, that is the difference between the genuine and the background rate, as 1 in approximately 200 h.

Table 2 Random Test, All Data

	Two-fold			Three-fold		
	Observed events	'Expected' events	Hours	Observed events	'Expected' events	Hours
All stations	242	270	1,114	6	3	586

We studied all the three-fold events in detail and Table 3 shows the date, time and type of each of the six events. All the three-fold events, except for that of July 28, 1970, were made up of pulses observed at three stations while at least one other station had an interference-free chart without any observable pulse. Also three of the events appeared only on one of the two frequency channels at Glasgow and/or Cambridge. The event of July 28 is exceptional because although it appears on both the frequency channels at Cambridge and Glasgow, it is not possible to draw any conclusions from the Dublin or Malta charts. An upper limit of 830 cm^{-3} pc can be placed on the dispersion measure of the source for this event. We conclude therefore that not only were no four-fold coincident radio pulses observed from the galactic centre in 209 h of observation but also that, with the possible exception of the July 28 event, no three-fold events of astronomical origin were observed in 368 h of observation. Weber has divided his events into four classes[4], roughly dependent on the energy of the event and the characteristic noise near the time of the event (see Table in ref. 4). If this classification is taken as some measure of the gravitational energy in the events, our upper limits on the rate of pulses suggest that there are no radio pulses associated with the two lower energy classes of event, which comprise more than 80% of the total. A consideration

Table 3 The Three-fold Events

Date (1970)	Time (UT) (h)	(m)	Class*	Comments
June 11	03	06	CDM$\overline{\mathrm{H}}$	Possible interference on D
July 2	20	40	DGH$\overline{\mathrm{M}}$	Galactic centre below horizon
July 11	02	14	DGM$\overline{\mathrm{CH}}$	G pulse on one channel only
July 23	21	29	GHM$\overline{\mathrm{C}}$	G pulse on one channel only
July 23	23	04	CGH$\overline{\mathrm{M}}$	C and G pulses on one channel only
July 28	20	09	CGH	Both channels on C and G†

* A bar indicates cases in which the traces were clean but there was no evidence for a pulse.

† This event had exceptionally large pulses which were recorded at the three stations at the same times within the limits of error, about 10 s. The mean time, 20 h 09 m 25 s UT, was very close to that of sunset. It was also within a few hours of the outburst[8–11] of Nova Scuti (1970) which happened to be in a sidelobe of our antennas at 20 h 09 m. A further occurrence which could conceivably be related was a transient disturbance in the ionosphere at 19 h 58 m 02 s on the same day, only 11 min earlier. This appeared on a record made at Glasgow of phase fluctuations in a 50 kHz standard frequency transmission from Czechoslovakia. A sudden phase advance of 1 μs in the received signal was followed by a rapid return to the normal phase within about 2 s. The fast recovery makes this disturbance very unusual; no others like it were found throughout the period of the GC observations.

of the sensitivity of our equipment places an upper limit to the radio energy in our bandwidth of 2.5×10^{-17} J m^{-2} per pulse or, on the assumption that the source has a spectrum similar to that of other non-thermal sources, of about 2.5×10^{-14} J m^{-2} per pulse in the radio band. This may be compared with Weber's[2] estimated 10 J m^{-2} per pulse of gravitational energy in a bandwidth of 0.017 Hz.

Several factors may complicate such a comparison. (i) The plasma surrounding the source may have a plasma frequency greater than 151.1 MHz, so that the source is completely screened, or the emitted radio spectrum may be quite different from that of "normal" sources. (ii) The time scale of the radio emission may be extended by comparison with that of the gravitational pulses, perhaps because of the emission mechanism or a large dispersion measure. For pulse lengths $T>1$ s our limiting flux density will be increased by a factor T. The time scale for radio emission from a collapsing object, for example, is likely to be quite different from that of the gravitational pulses. The first of these must originate in the outer regions of the object whereas the second will be associated with the core regions. The recently proposed LeBlanc–Wilson model[5] of stellar collapse, however, implies a time scale of the order of a few tenths of a second for the emission of most of the radiated energy; (iii) Weber's source or sources may not have been in our beams during the period of observations, because the beam width of his antennas is greater than ours.

Because of these possibilities we emphasize that our findings do not invalidate Weber's results, but simply show that there are no radio pulses from the galactic centre at rates comparable with his rate of detection of gravitational events. When the actual times of gravitational events are published, a detailed comparison with radio observations will be possible.

Partridge[6] has described an unsuccessful search for microwave pulses associated with Weber's events, and Bahcall and Davis[7] have set an upper limit on the neutrino energy emitted.

We thank Mr W. McKellar and Dr J. White for the construction and maintenance of the antennas at AERE and UCD respectively, Mr A. McKellar for construction of much of the equipment at Glasgow, and Miss R. Kavanagh for the analysis of charts at UCD and for handling the computer program. We also thank Lady Weipers, Supervisor of Cochno Veterinary Field Station, Glasgow University, for providing an observing site and facilities. R. F. H. acknowledges financial assistance from a CSIRO Fellowship.

Rapid Optical Variability of the Source PKS 1514–24

THERE are two cases in which radio sources have been identified with optical objects previously known as variable stars: the Seyfert galaxy 3C120 with the star BW Tau (ref. 1) and VRO 42 22 01 with BL Lac (ref. 2). As a systematic search for possible new concidences, 807 variable stars were selected from the *General Catalog of Variable Stars*[3] and its first supplement[4] using the following criteria: (i) type given as irregular or unknown; (ii) no spectral type given; and (iii) galactic latitude $|b_{\mathrm{I}}|>10°$. This list was checked for coincidences against *A Master List of Radio Sources*[5] and the fourth instalment of the Ohio survey[6]. Only two coincidences were found.

The source ON 231 lies close to the star W Com (variable from magnitude 13 to 15.5, type unknown). The position of W Com was measured on the Palomar Sky Survey, and a more accurate radio position was kindly provided by M. Davis. As Table 1 shows, the discrepancy is about two standard errors in both coordinates.

The image of W Com on the Palomar Sky Survey is starlike, but a faint nebulosity seems to extend toward the radio position. A more accurate radio position is needed to ascertain the identification.

The source PKS 1514–24 has been identified by Bolton *et al.*[7] as an E galaxy. This object had been discovered previously as

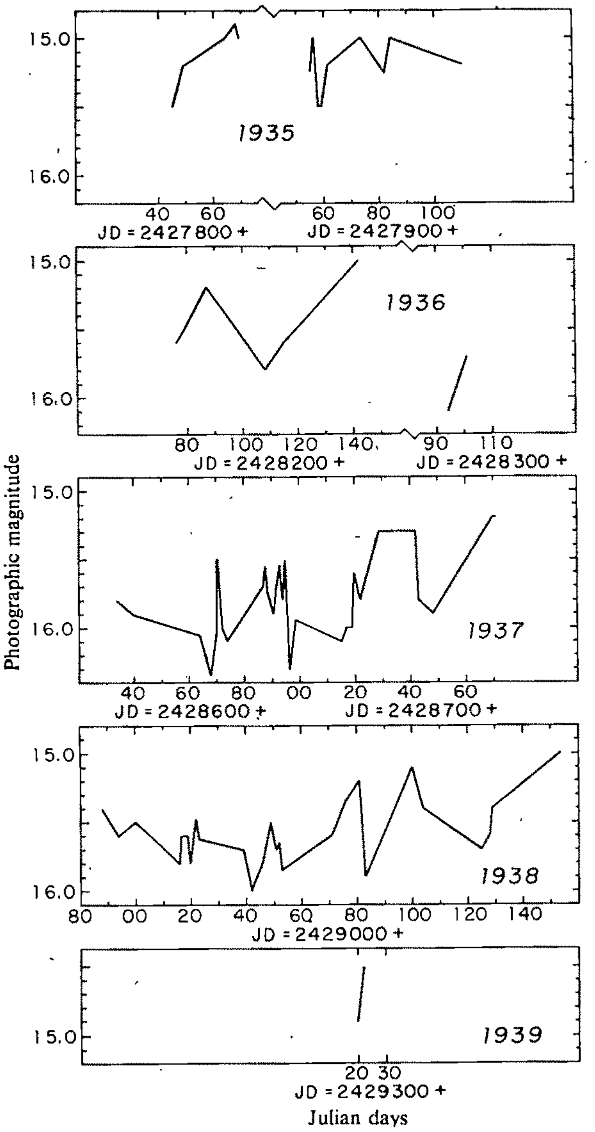

Fig. 1 Light curve of the variable star AP Lib.

the variable star AP Lib by Ashbrook[8]. The position of the star measured on the Palomar Sky Survey agrees with the first optical position given by Bolton *et al.*[7] and with the various radio positions. A second optical position given later by Bolton[9] is clearly in error.

Table 1 Positions of W Com and ON 231

	R.A. (1950.0)	Dec. (1950.0)
W Com	12 h 19 m 01.2±1 s	+28° 30′ 26″ ±10″
ON 231	12 h 18 m 58.2±2 s	+28° 29′ 24″ ±30″

The measurements by Ashbrook cover the period from February 1935 to March 1939, and the resultant light curve is shown in Fig. 1. The magnitude usually lies between 15 and 16, with limiting values of 14.5 and 16.4. There are periods of very fast and chaotic variations; variations up to 0.8 magnitude on a time scale of a few days are common. For some nights, several plates a few hours apart are available and yield variations of 0.7 magnitude in 5 hours on June 8, 1937, and 0.6 magnitude in 3 and 5 hours on May 3 and 4, 1938. In addition to these measurements, visual inspection of fifty-three patrol plates at Harvard College Observatory covering the interval from February 1939 to July 1951 shows high activity in July 1941, July 1944, and May 1945. The maximum brightness seems to reach $m_{\rm pg} \simeq 14$ in 1944.

The very fast variations of AP Lib resemble those of the peculiar object BL Lac, which are unique in that they are more rapid than those of any QSO or Seyfert galaxy. The amplitude of the variations of AP Lib is somewhat smaller[10,11] than those of BL Lac, but the observations are not as many or as closely spaced as in the case of BL Lac. VRO 42 22 01 has no measured low frequency component, but a spectrum which always increases toward high frequencies. The flux of PKS 1514–24 is constant (about 2 flux units) from 1,410 to 5,009 MHz (refs. 12 and 13). There is a strong discrepancy between the 408 MHz flux measured at Parkes (5.3 flux units, ref. 12) and at Molonglo (1.9 flux units, ref. 14). The Molonglo flux is likely to be more reliable[15], thus giving for PKS 1514–24 a flat spectrum over the observed frequency range. On the other hand, the disagreement about the 408 MHz flux could be an indication of radio variability.

Assuming that the extinction at the galactic latitude of AP Lib ($b_{\rm II} = 28°$) is 0.6 magnitude, and the mean flux density of VRO 42 22 01 is 6 flux units at 2,695 MHz, then the ratio of optical to radio (at 2,695 MHz) luminosities is about two times greater for BL Lac.

Photometric and spectrographic studies, as well as a search for radio variability, are needed to establish the properties of AP Lib and its possible similarity to BL Lac.

I thank Martha Ashbrook for making data available to me and Martha Liller for help in examining the Harvard patrol plates. NRAO is operated by Associated Universities, Inc., under contract with the National Science Foundation.

Interplanetary Lyman–Alpha: Theory and Experiment

DISCUSSIONS of the results of the Vela 4 scattered Lyman-α experiment[1] by Bowers[2] and Blum and Fahr[3] contain errors and misinterpretation which we believe should be pointed out promptly. The use by both authors of "Vela 7" to refer to the Vela Launch 4 spacecraft also leads to confusion because the experimental data have been published as Vela 4 data.

Bowers asserts that Chambers *et al.*[1] imply that the source of the Lyman–α radiation observed is a shock front which is luminous at Lyman–α. Actually ref. 1 clearly states that the observed radiation is assumed to be solar Lyman–α, resonantly scattered from neutron hydrogen, and that the asymmetry in the observed radiation is related to asymmetry in the distribution of the scattering hydrogen. Although Blum and Fahr do not mention Lyman–α radiation in the publication[4] referred to by Bowers, their further published work[5] also attributes the observed Lyman–α to scattering of radiation originating at the Sun.

Bowers plots the region of observation of the Vela 4 experiment on his galactic line-of-sight plot (partly reproduced in Fig. 1), then indicates the location of the maximum in the observed Lyman–α radiation and notes that the maximum falls on the Milky Way. The path shown by Bowers, however, does not apply to the Vela 4 Lyman–α observations. The detectors in question were mounted on the centre column of the spacecraft and aligned to look outward along the spin axis. The satellites were Earth-oriented by maintaining the direction of the spin axis towards the centre of the Earth, and the observed region of the sky is mapped by the orbit of the satellite. The correct observed region is approximately 15° on either side of the orbit as shown in Fig. 1. Also, the conveniently localized maximum flux region shown by Bowers has no basis in fact. The broad maximum of the Vela 4 data, an example of which is shown in Fig. 2, occupies at least one third of the orbit. There is no obvious indication of crossing the Milky Way in any of the Vela data except, in some cases, a minor peak of amplitude about 15 Rayleigh near $\alpha = 105°$. The peak is consistent with ultraviolet measurements of εCMa by Stecher[6]. Further evidence of the lack of enhanced emission in the direction of the Galaxy is provided by the Mariner 6 data[7] and the OGO 5 measurements of Thomas and Krassa[8].

In attempting to relate theoretical calculations of the intensity of scattered Lyman–α radiation observed from the Vela orbit with experimentally obtained plots, Blum and Fahr[3] have treated the Vela 4 points as mean values to fit the smooth curve shown in Fig. 3; actually the plotted points are lower step points. The Vela 4 Lyman–α instrument output is telemetered in rather coarse digital form so that the observed signals lie in an interval between possible output steps. The lower step has been arbitrarily used because the experimental error in the Lyman–α experiment is large compared with the interval between steps. Much of the error, however, originates in the determination of the flux used for laboratory calibration so that the principal part of the error is proportional to the flux observed. Thus the shape of the plotted data is more significant than its absolute value, and a curve passing between a pair of points more accurately represents the data. If the curve of Fig. 3 were made to fit the data in the manner just described, the shape would be somewhat different from that depicted by Blum and Fahr and the correlation between theoretical predictions and measurements may not be as good as it appeared.

Re-evaluation of the Palaeogeographic Argument for an Expanding Earth

EGYED[1] has inferred that the Earth was expanding at a mean rate of 0.5 mm yr^{-1} during Phanerozoic time. The evidence on which he based this conclusion was taken from two series of palaeogeographic maps showing the distribution of land and sea since the early Cambrian, by Strakhov and H. and G. Termier respectively. With the aid of a planimeter Egyed estimated the percentage of continental areas covered by the sea for successive geological periods and was able to demonstrate clearly a secular decline since the early Palaeozoic with the more or less regular downward trend having superimposed on it a series of shorter phase oscillations.

As the volume of ocean water is hardly likely to have declined

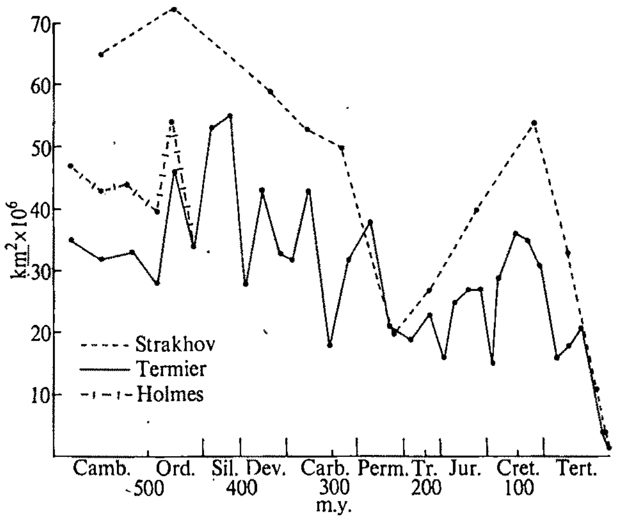

Fig. 1 Areas of continents covered by sea in Phanerozoic time.

during Phanerozoic time, and might indeed have been augmented by a small percentage, Egyed argued that the facts could only be explained by a gradual increase in the Earth's volume, so that ocean water drained more or less progressively from the continents into the growing oceans.

The essential palaeogeographic facts are not in dispute. As plotted in Fig. 1, the two groups of data, though differing appreciably, are in accord as regards the decline through time of areas of the continents inundated by seawater, the only notable (but temporary) reversal of this general trend being in the late Cretaceous. Of the two sets of data, that of the Termiers, based as it is on more numerous time intervals, gives a more accurate idea of the oscillatory nature of the change. The modification of the Cambro-Ordovician data proposed by Holmes[2] is accepted here. Apart from the areas of metamorphic rocks in Africa and elsewhere that were probably marine sediments originally, missed by the Termiers, it should be borne in mind that the older the rocks the greater is the likelihood of their having been removed by subsequent erosion or deeply buried beneath younger sediments beyond the limits of intensive drilling. For these reasons the amount of the secular decline is more likely than not to be underestimated in most palaeogeographic maps.

Both Egyed and those who have accepted his argument[2–4] have failed to consider an alternative explanation of the facts, that the average thickness of the continents has increased slightly through the course of the Phanerozoic. The isostatic uplift consequent on such increase would inevitably have the effect of reducing the area of marine inundation. There are grounds for believing that changes of this sort might, in fact, have taken place.

In the first place, many ancient shields have persisted for millions of years as positive areas and sediment sources. Maintenance of relief following removal of sediment would naturally result from isostatic adjustment, but obviously this could not persist indefinitely because the shields would achieve isostatic stability with low relief and relatively thin crust. In fact such shields often have crustal thicknesses greater than the average[5], even though metamorphic rocks of granulite facies may be exposed at the surface. Extensive tracts of the Archaean shields consist of the so called Greenstone Belts, which are believed to signify appreciably thinner crusts in early Pre-Cambrian times, perhaps only 12–15 km. This is based on various data, including the chemistry of the metabasalts and comparisons with present day island arcs[6]. The implication is that the shields have undergone a progressive "sialic underplating" since the early Pre-Cambrian as a result of slow differentiation in the underlying mantle.

In the second place, geochemical and other data suggest that the andesites of island arc complexes and the associated granitic batholiths in regions such as western North America originate primarily by differentiation of basaltic magmas arising from descending slabs of ocean floor along subduction zones, with only limited contamination by continental crustal materials[7,8]. At the rate of thickening implied by volcanicity since the Miocene, the whole of the Japanese crust could have been generated in about 3×10^9 yr[7]. This process provides a ready mechanism for creating continents which is consistent with the tenets of plate tectonics. Many former geosynclinal regions emerged from the sea following major orogenies and became incorporated into cratons bordering the ancient shields and so something more than lateral accretion is involved. Sutton[9] has incorporated such facts into his notion of chelogenic cycles, whereby tectonically mobile belts characterized by flysch-type marine sedimentation and vulcanicity are transformed into stable shield areas or cratons, on which only continental or shallow marine sediments were laid down, the latter often only at the margins. The conversion of the Caledonian geosyncline of the North Atlantic region into the "Old Red Sandstone Continent" in Devonian times is a good example, because it persisted as a positive area until well into the Mesozoic, when it was disrupted by the drifting apart of North America and Europe.

An approximate estimate of the amount and rate of thickening of the continental crust can be obtained by considering estimates of the changes in relative position of sea level in the past 600 million yr or so. Egyed[1] estimated that sea level in Cambrian times was about 500 m higher than today, if Strakhov's data were to be relied upon, or 275 m higher in the middle Ordovician, using the Termiers' data. Kuenen[10] was able to show from the world hypsographic curve that under present conditions a eustatic rise of 100 m would flood about 1/4 to 1/5 of the continents and a rise of 200 m nearly 1/3. He considered that the present continents have abnormally high relief and so thought that at most periods in the past a 100 m rise would flood more than 1/3 of the continental area. The palaeogeographic maps available to Kuenen seldom showed more than 1/3 of the continents submerged, and he concluded that the biggest transgressions did not involve eustatic rises of more than 200 m.

These figures suggest that the Termiers' data might be more accurate than those of Strakhov. An independent check on the maximum area covered by the Jurassic seas[11] also gives a figure (24%) much closer to that of the Termiers (27%) than Strakhov (39.5%).

If we take 300 m as a figure of the right order of magnitude for the amount of secular lowering of sea level since the early Palaeozoic, this would be accounted for by an average thickening of the continental crust of perhaps twice this amount. Such a figure implies an increase of only about 1 mm in 10^3 yr, with no more than about 2% of the present average thickness of the continental crust being added in the last demi-eon. Modest, almost negligible, change of this kind could be accounted for readily by the processes previously discussed. With such a plausible alternative interpretation being available the simple palaeogeographic argument for an expanding Earth cannot reasonably be sustained.

The shorter phased eustatic oscillations superimposed on the gradual lowering of sea level, given crude and oversimplified expression in Fig. 1, are to be accounted for in other ways. Whereas glacially controlled eustatic changes dominated Pleistocene palaeogeography it is doubtful whether the melting and freezing of polar ice played more than a minor role further back in time. Thus even the well documented late Palaeozoic Ice Age of the southern continents had no clearly perceptible large scale effect. On the contrary, the apparent disappearance of the ice sheets at the close of the Palaeozoic coincided with a pronounced marine regression rather than a transgression. The dominant control was much more likely to have been variations in the cubic capacity of the ocean basins due to the uplift and subsidence of mid-oceanic ridges and trench systems[12]. Evidence is now accumulating to suggest that uplift and subsidence of mid-oceanic ridges correlate respectively with increases and decreases of seafloor spreading rates[13]. The more fundamental control is presumably temporal variations in heat flow from the mantle.

The two most notable departures from a more or less gradual lowering of relative sea level in the Phanerozoic are the pronounced regression of the late Permian and early Triassic, and the equally striking transgression of the late Cretaceous. This is brought out more clearly in the less accurate Strakhov curve of Fig. 1. In fact both curves probably over-estimate by a considerable margin the area of continent covered by the sea at the close of the Palaeozoic, which was closer to the minimal values of the Pleistocene than anything before or since. Both phenomena probably relate to significant plate movements. Valentine and Moores[14] have argued that the suturing of Palaeozoic continents to form "Pangaea II" would be a sufficient cause of regression in the late Permian. With regard to the late Cretaceous, a major transgression could have been produced by one, or both, of the following factors: an acceleration of spreading rate or an increase in the length of the oceanic ridge system as significant dispersal of both northern and southern sectors of Pangaea got under way. The probable timing of continental breakup[15] suggests the latter cause to be sufficient.

I thank Dr E. R. Oxburgh and Dr S. W. Richardson for their helpful comments.

Laser Radar Reflexions and Downward Infrared Flux Enhancement near Small Cumulus Clouds

WE wish to report some interesting simultaneous enhancements of backscattered laser pulses and the downward infrared flux in regions of clear air surrounding small cumulus clouds. The observations were made at Adelaide, South Australia, in March 1970, and at Aspendale, Victoria, in February 1971, but at Aspendale only a radiometer was operated.

We used a ruby laser (0.694 µm) with a pulse length of 0.5 µs, and the transmitter and receiver beamwidths were 1.0 mrad and 5.7 mrad respectively[1]. The field of view of the radiometer (10–12 µm) was 6 mrad and it had a minimum detectable radiance of 0.002 mW cm^{-2} sr^{-1} with an output bandwidth of 0.1 Hz (C. M. R. Platt, private communication). Both instruments pointed vertically upwards and were 100 m apart at Adelaide.

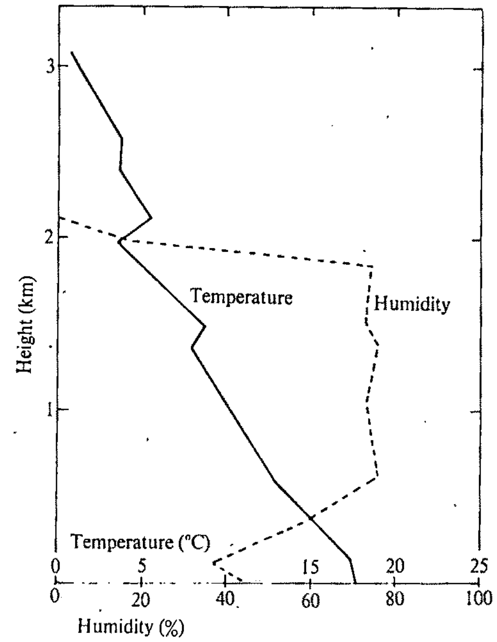

Fig. 1 Temperature and humidity profiles.

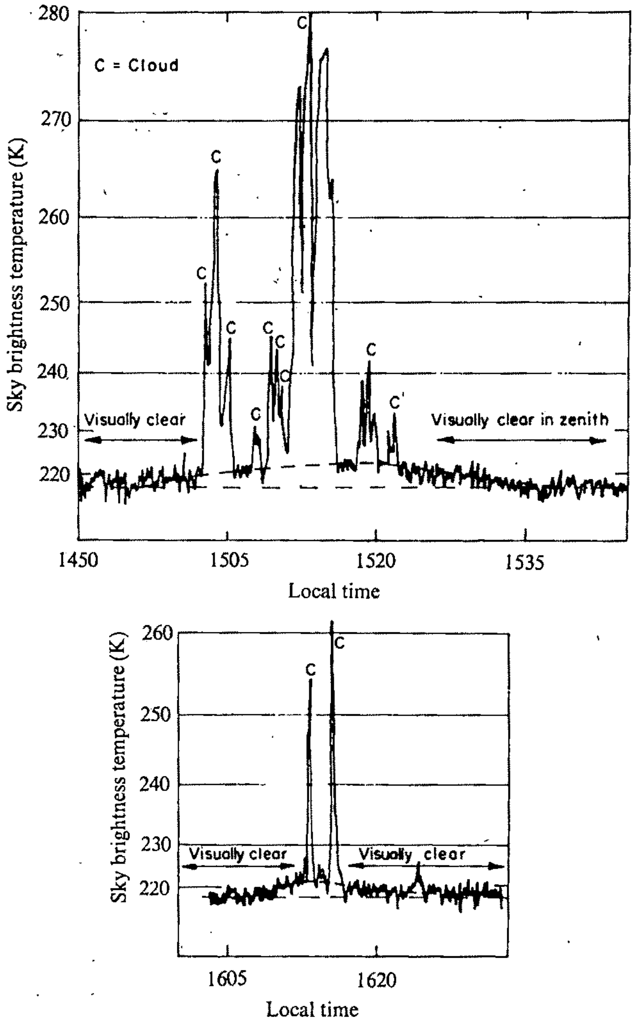

Fig. 2 Zenith sky brightness temperature (10 µm–12 µm).

In clear skies, backscattered radiation at the 0.694 µm wavelength of the laser is due to Rayleigh scattering from molecules and Mie scattering from aerosols, and the backscattered intensity is, of course, greatly increased when low cloud is present. On the other hand, atmospheric water vapour is responsible for the downward radiant flux at 10–12 μm when the sky is clear, although there is a small contribution from aerosols.

The weather at Adelaide was controlled by a cool southerly maritime airstream that was moist under an inversion at 2 km but dry aloft (Fig. 1). Small cumulus clouds were forming in groups and drifting over the site, but there was no rain. Conditions at Aspendale were similar.

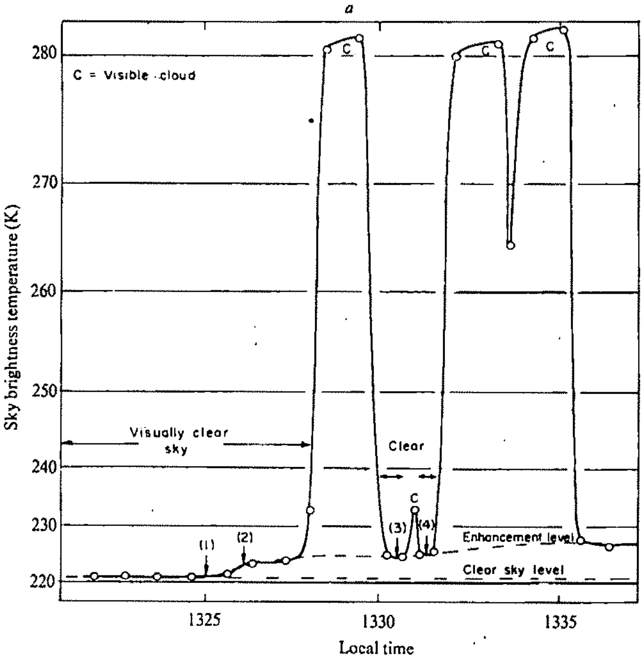
Fig. 2 shows the infrared enhancements that occurred around groups of cumulus. The arrival of visible cloud edges (*c*) is marked by sharp increases in downward radiance, but the interesting point is the slow increase in radiance that occurs outside the visible clouds. The increased radiance persists between clouds, but reverts to the original level after the passage of a group of clouds.

Fig. 3 compares the radiometer measurements with simultaneous laser radar (lidar) observations. Aerosols must be responsible for most of the observed variation in the backscattering coefficient I′(*h*) which is normalized to unity at 2 km. This is because between 0.4 and 2 km the molecular backscatter would only vary by the factor 1.14 (because of the pressure change).

The enhancement of I′(*h*) is very marked, particularly in the region of the cloud base which was estimated from the measured radiance and radiosonde data and is correct to 200 m, and it is clear that the enhancement continues in the gaps between clouds. Fig. 3 also shows reasonable agreement between the onset of the lidar enhancement and the increase in radiance. In this figure, in contrast to Fig. 2, the clouds have fairly constant radiances, indicating that they must have been optically thick.

The same pattern was observed four times on March 19, 1970, as four different cloud groups passed overhead. Fig. 4 shows another example.

The most likely explanation is that hygroscopic aerosols are taking up water and swelling under conditions of increased humidity as the air below the condensation level is lifted, and cools. That must be why the maximum enhancement of backscatter occurs near the level of the cloud base, the condensation level. Particles at 95% humidity have about twice the radius of those in the dry state, and towards 100% humidity the increases are from three to ten depending on the nature of the



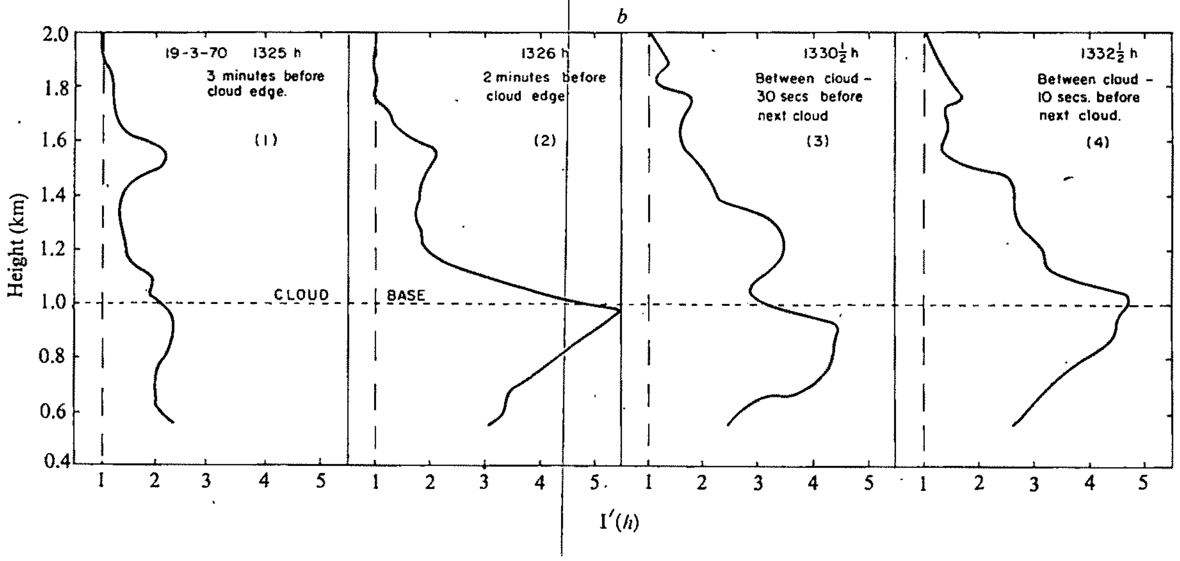


Fig. 3 *a*, Zenith sky brightness temperature (10 μm–12 μm). *b*, Lidar intensity–height profiles (normalized at 2 km).

particles[2,3]. And because the increased volume is composed of liquid water, which is highly absorbing in the infrared, the emissivity of the particles is increased. Clearly the increase in particle size and change in refractive index affect the lidar observations. Table 1 shows the relative increases in backscattered intensity predicted by Mackinnon[4] for the case when half the aerosols in both continental and maritime distributions are hygroscopic. These results can be compared directly with experiment as the morning humidity at Adelaide was 75% at 1 km, and the increase in aerosol backscatter measured by us agrees approximately with that predicted by Mackinnon if the humidity approaches 100%.

Table 1 Humidity Effects on Backscattered Lidar Power from Aerosols, Hygroscopic Aerosol Radius and Infrared Emissivity at (10–12 μm)

Relative humidity H (%)	Ratio of aerosol backscattered power at H to that at 75% humidity[4] C	M	Ratio of aerosol radius at H to that at 75% humidity C	M	Increase in emissivity E_λ C	M
96	1	2	1.7	2	0.0025	0.002
97	1.3	4				
98	1.5	4.5				
99	3	5	2	3.5	0.003	0.005
100	~5	~10	3	10	0.01	0.035

Mean observed emissivity=0.02.

C, Continental distribution; M, maritime distribution.

The corresponding change in infrared emissivity for a homogeneous layer of aerosols has been computed using similar continental and maritime distributions to those used by Mackinnon. For an optically thin layer, and neglecting scattering, the emissivity E_λ is given by $(1-\tau_\lambda)$, where τ_λ, the optical thickness, has been computed from Mie's theory. Computed values of E_λ for a 300 m layer are shown in Table 1 and compared with the mean observed value. It can be seen that the theoretical emissivity approaches the measured emissivity for either distribution if the relative humidity approaches 100%. The lidar results seem to favour the continental distribution although the actual value of $I'(h)$ at the condensation level is greater than that shown because of the low laser pulse resolution. At a coastal site such as Adelaide one would expect the aerosols to be a mixture of continental and maritime types, and the theoretical computation certainly gives order of magnitude agreement with observation.

It should be pointed out that the infrared emissivity will also increase near the clouds if the specific humidity of the air (humidity mixing ratio) is increased, due either to entrainment of moist air or the evaporation of water droplets near the cloud edges through mixing with the surrounding air. For example, the emissivity of a layer 300 m thick would increase by 0.01 if the specific humidity changed from 5.7 g kg^{-1} (early morning value at the cloud base) to the saturated value of 7.3 g kg^{-1} at the cloud base temperature. In all probability the infrared enhancement is due to both swelling of aerosols and increased water vapour, but the lidar enhancement can only be due to an increase in aerosol size in this model. But there is also the possibility of an increase in aerosol density near the clouds because of updrafts. Even if the aerosols remained dry, the density increase might account for the observed increase in lidar backscatter intensity, but the infrared emissivity increase would be considerably less than that observed. (This was verified by combined observations of aerosols in dry conditions.) Thus it seems that the aerosols must also swell to account for the large emissivity change.

Table 2 Average Extent of Lidar and Radiometric Enhancement around Small Cumulus Cloud Groups

Date	Windward (km)	Leeward (km)
March 19, 1970	1.3 (4)	—
February 10, 1971	3.4 (3)	5.8 (2)

Figures in brackets give number of observations.

Table 2 summarizes the spatial extent of the observed enhancement. The phenomenon carries with it the implication that in

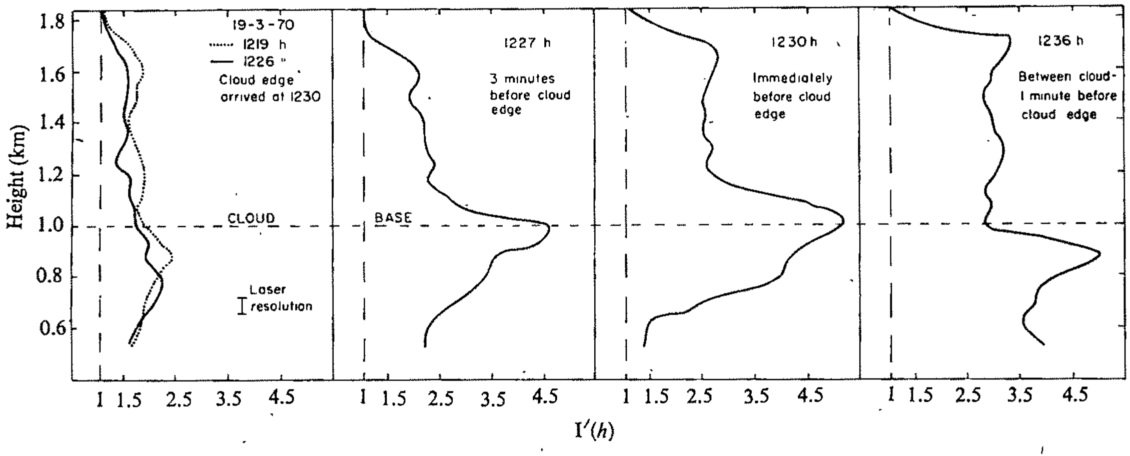

Fig. 4 Lidar intensity–height profiles (normalized at 2 km).

some cases there is a broad region of uplift in and surrounding groups of small cumulus clouds. So the clouds seem to be fed from below over a broad region.

On a few occasions, however, the effect was absent, or much reduced. This may be because when cumulus clouds are decaying the updraughts are replaced by downdraughts[5].

It is interesting that Wilkins *et al.*[6], using a wavelength difference technique, observed haloes around cumulus clouds in visible and near infrared photographs taken from Apollo 9 (SO-65). The haloes were also evident in a photodensitometer profile across a cloud bank image, and extended 1 km from the cloud edge. It seems likely that these authors and ourselves are observing the same phenomenon.

We thank Dr W. G. Elford for cooperation in making these measurements possible.

Effect of Time on the Mechanical Behaviour of Failed Rock

When a rock specimen is compressed from an initial intact state to complete collapse, the failure locus can be traced out on a force–displacement diagram as shown by the solid line in Fig. 1*a*. Until recently, this curve was followed in experiments only to the point where the compressive strength was reached; the rock then disintegrated violently. This catastrophic failure is caused by the elastic unloading of the testing machine after the peak of the force-displacement curve and is not an intrinsic property of the rock. The elastic strain energy released by conventional "soft" testing machines exceeds the amount of energy required to break the rock and the excess energy is liberated in the form of kinetic energy. Uncontrollable failure can be avoided by the use of "stiff" testing machines which store very little strain energy[1–6], or by closed loop servocontrolled testing machines which can reduce the load faster than the specimen breaks[7–9].

When the force–displacement curve is scaled by the cross-sectional area and length of the specimen, a complete stress–strain curve is obtained. For the design of structures in rock it is important to establish whether this curve is a material property or varies with the experimental conditions. In particular, the effect of time on the complete stress–strain curve must be established. It is known that the part of the stress–strain curve of rock before the peak is time dependent[10–15] and it is likely that the section after the peak is even more sensitive to time because the specimen is in a continual state of progressive collapse.

All research on the time dependent behaviour of rocks before the peak of the stress–strain curve has been carried out with reference to strain rate and creep. The only research on the effects of time in the region of the curve after the peak[15] was concerned with the effect of strain rate on the complete stress–strain curve for sandstone. Bieniawski[15] found that the descending side of the stress–strain curve became steeper as the strain rate increased. He also attempted to study the creep of failed rock but could not achieve a constant stress condition because the rock deformed along the elastic unloading characteristic of his testing machine. In soft or stiff mechanical testing machines, only a limited range of boundary conditions can be achieved precisely. This is presumably the reason why the effects of strain rate and creep have been studied exclusively. With the advent of closed loop servocontrolled testing machines, it is now possible to achieve almost any required boundary conditions and all aspects of the effect of time on the complete stress–strain curve for rock can be studied.

In a servocontrolled testing machine the specimen is loaded by a hydraulic actuator and the actuator pressure is adjusted by means of a servovalve. A feedback signal (t) representing some experimental condition of the specimen is electronically compared with a programme signal (p) representing the required condition. If a difference exists, an error signal operates the servovalve and the pressure on the rock is adjusted until t coincides with p. The mode of operation of the closed loop is shown in Fig. 1*b*. The comparison of t and p can be made 10,000 times per second and the response time of the system can be as low as 0.002 s. If a constant stress rate is

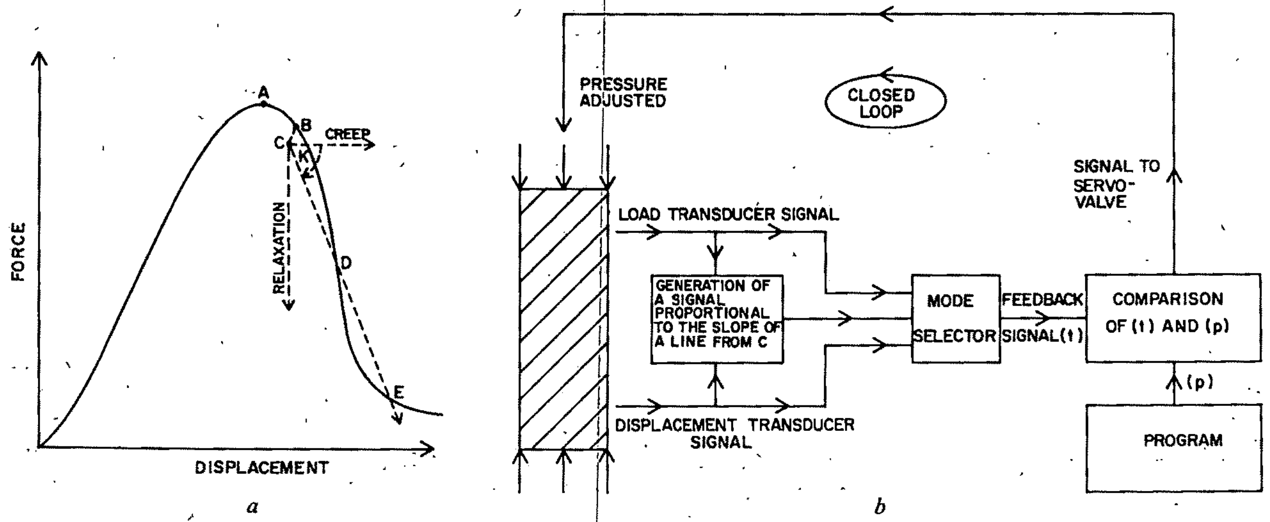

Fig. 1 *a*, Typical complete force–displacement curve for rock; *b*, closed loop servocontrolled system.

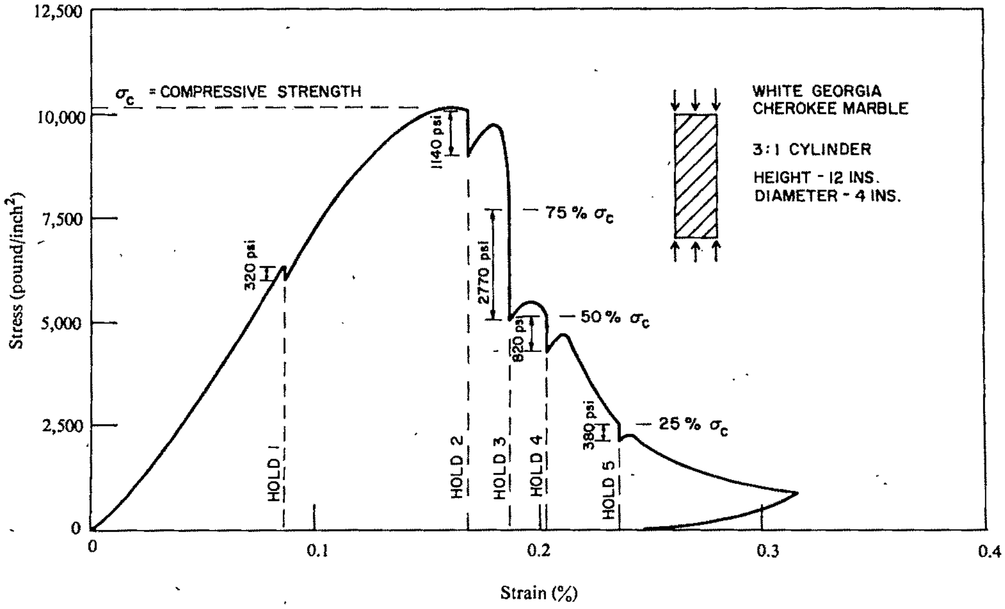

Fig. 2 Stress relaxation in failed marble.

required, the feedback signal is generated directly by a load cell and p linearly increases with time. The rock will fail very violently at the peak of the stress–strain curve in these conditions because the machine attempts to increase the stress as the rock is breaking. When a constant strain rate is required, the feedback signal is generated by a displacement transducer and again compared with a linearly increasing programme signal. As the specimen displacement is linearly increased by the operation of the closed loop, the associated stress rises to a maximum and then slowly falls as the complete stress–strain curve is traced out. To study creep, the programme is stopped at any required stress level with the feedback signal corresponding to the load. A constant stress level is then achieved by the operation of the closed loop. To study relaxation, the programme is stopped at any required strain value and the feedback signal then corresponds to the specimen displacement.

An example of stress relaxation is given in Fig. 2 which is a complete stress–strain curve for white Georgia Cherokee marble loaded in uniaxial compression. The specimen was strained at room temperature at a constant rate of $1.5 \times 10^{-6}\ s^{-1}$ except for the five points on the displacement axis at which the displacement was held constant for one hour. The first displacement hold was made during the apparently linear ascending portion of the force–displacement curve. The remaining four holds were made just after the peak and at 75%, 50% and 25% of the compressive strength. The amount of stress relaxation along each of these constant displacement lines is shown in Fig. 2. When the strain is increased after a hold, the curve seems to rise to a continuation of the original curve, indicating that the descending part of the complete stress–strain curve is not affected by this type of variation in the strain increase. The same result was obtained by Bieniawski[15] for time deformation of sandstone along the 1,110 MN/m unloading characteristic of his stiff testing machine. The maximum amount of stress relaxation occurred at the displacement corresponding to 75% of the maximum stress. This suggests that stress relaxation will be a maximum where the stress–strain curve is steepest, that is, when the relaxation line is closest to the failure locus.

Both creep and stress relaxation are phenomena associated with very specialized applied boundary conditions. In practice, for example, a mine pillar left for a period of time, the rock is subjected to neither a constant load nor a constant deformation but to a condition dictated by the unloading of the surrounding rock. To study time-dependent deformation along the line of arbitrary slope $-k$, both the load and displacement transducer signals must be used to generate the feedback signal. If the experimental force–displacement coordinates are above the line *CE* in Fig. 1*a*, the error signal should cause the servovalve to reduce the pressure. Conversely, if the coordinates are below *CE*, the pressure should be increased. The operation of the closed loop with a slope feedback thus allows a study of time deformation along any such line. If a specimen is strained to a point *B* on the complete stress–strain curve and then unloaded slightly to a point *C* as shown in Fig. 1*a*, the closed loop operation can be modified to study any type of time dependent behaviour. A constant stress condition would result in creep back to the failure locus. A constant displacement condition would result in stress relaxation to a safer condition (provided the stress–strain curve increased monotonically). If the machine was programmed to follow the line *CDE*, the specimen could deform to the failure locus at *B*, drop quickly to *E* and then stabilize at some lower stress value.

The ideas and data presented in this communication were obtained during research for the Advanced Research Projects Agency (principal investigator, Professor C. Fairhurst).

Optical and Acoustic Detection of Ball Lightning

THE recent controversy about ball lightning[1-4] stimulates me to report an observation of such an event, which occurred in September 1963.

This event occurred at approximately 11 a.m. in the entrance hall of the Plöckenhaus, a restaurant below the Plöckenpass in the Carnic Alps (Austria). Students from a field trip of the Geology Department of the Universität Heidelberg were staying inside this restaurant because of a thunderstorm with heavy rain. Some of the students were sitting in the guest room and some were standing in the entrance hall. The outside doors of the house were open. The door between the guest room and the entrance hall was, as I remember, closed. The floor of the entrance hall consists of heavy limestone plates. Also in the entrance hall was a St Bernard dog, lying on the floor.

Suddenly, through the open outside doors, a whitish yellow ball appeared just above the floor. It was slightly larger than a tennis ball, and its speed was about that of a walking person. The light ball moved about 2 m in the direction of the dog and finally exploded with a loud bang, like a gun shot. The dog jumped away as it saw the moving light ball. All the people in the entrance hall (about five) saw the ball and heard the bang. People from the guest room came out to ask what happened, because they had heard the bang. I do not remember feeling any radiation heat from the bang, nor smelling anything after the explosion. We, the bystanders, explained this event as a "Kugelblitz" (ball lightning).

The optical observation by several people, the reaction of the dog, and the acoustic perception of the people in the adjacent room are hard to explain by the optical illusion hypothesis for ball lightning.

On Fireballs

THE recent discussions on fireballs prompt me to put on record that a few years ago I saw one when staying at a villa near Malcesine on the east shore of Lake Garda in Italy.

A bad thunderstorm had been raging and, because I still harbour a childish phobia about looking at lightning, I had not been looking out of the window. But as the storm slackened and was passing away, I did look out and saw a brilliant ball of white fire "sitting" still on one of the pylons carrying power lines along the east side of Garda, only a few hundred yards from our villa. It sat on one of the horizontal cable bearing cross-beams, and its diameter was less than the vertical distance between the cross-beams. There could be no question of my, or my friends, seeing an after-image of lightning, particularly as I never look at lightning myself.

We looked at the fireball for some time, but as it did nothing but sit still, we lost interest; when we looked out later, it had disappeared.

Crystal Structure of the Visual Chromophores, 11-*cis* and all-*trans* Retinal

THE visual chromophores, 11-*cis* and all-*trans* retinal (Fig. 1), are present in both rod and cone cells of vertebrate retinas and in the corresponding organs of insects and crustacea[1]. The isomerization of the 11-*cis* isomer to the *trans* form may be the only step in the visual process which is initiated by light; several succeeding changes in the visual pigment are known to occur in the dark[2,3]. In spite of their importance in vision, the conformation of the chromophores have not been determined. Their three dimensional configurations in the crystalline state are presented in this communication.

Theoretical chemists have attempted to explain the stability and predict the structure of 11-*cis* retinal. Recent calculations predict a very slight difference in energy for the two isomers[4-6], which is consistent with thermodynamic measurements[7]. However, the structural models proposed differ from the conformation found in the crystal*. In these calculations, bond distances and angles characteristic of *trans*-carotenoids were assumed, and various conformational possibilities were explored by varying torsional angles about bonds. The discussion below indicates that several small but significant distortions in bond angles may be critical in the folding process.

The collection of X-ray diffraction data requires a relatively stable crystal. Fortunately, crystals of the *cis* isomer are more stable than its solutions, which easily isomerize at room temperature. Preliminary attempts to collect data indicated that a special environment was needed. The four-circle goniostat of an automatic diffractometer was enclosed in a light-tight container maintained at 16–17° C and continuously purged with dry nitrogen. In this manner, it was possible to collect 2,345 integrated intensities from one freshly synthesized crystal over about 4.5 days. The data were corrected to compensate for a 20–25% downward drift in monitored intensities. A total of 2,995 independent reflexions was also collected from the *trans* isomer.

(The 11-*cis* isomer formed twinned crystals in space group $P2_1/c$ with $a=7.540$, $b=10.666$, $c=22.102$A, $\beta=95.19°$, and four molecules/cell. The *trans* isomer crystallized in $P2_1/n$, with $a=14.961$, $b=8.279$, $c=15.316$A, $\beta=104.87°$, and four molecules/cell. Both isomers were crystallized from petroleum ether (Baker Analyzed Reagent, boiling point 36–37.5° C). Crystallization was initiated at 5° C and completed at −20° C. The *cis* isomer was synthesized when needed from commercially available *trans* retinal, using the methods of refs. 8 and 9.) The unit cell parameters found for the *trans* isomer agreed with those reported by Kuwabara *et al.*[10].

Approximate positions for the carbon and oxygen atoms of the two isomers were established by the symbolic addition procedure[11]. Refinement of the atomic positions and their apparent anisotropic thermal parameters was accomplished with standard least squares refinement programmes. For both isomers, the hydrogen atoms of the chain and most of the methyl hydrogens were located in difference maps. Based on cell data the agreement factors, that is the crystallographic R-factors, are at present 12.6% (11-*cis*) and 9.9% (*trans*). Further refinement and full hydrogen determinations seem feasible, and the final results, along with more crystallographic detail, will be published later.

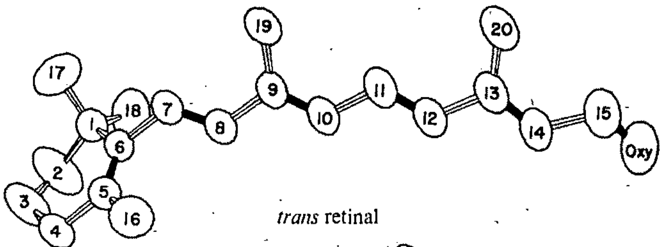
The suggested three dimensional structures of the two retinals are presented in Fig. 1. The all-*trans* retinal chain is planar,

---

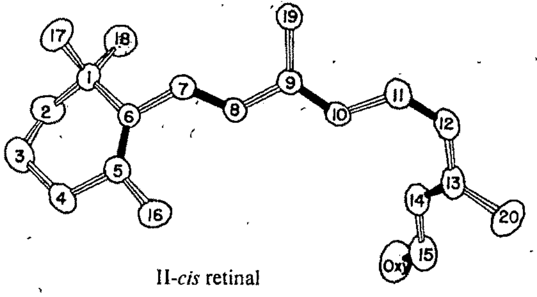
* Since our manuscript was prepared an article has appeared[16] which does theoretically propose a ground-state configuration for 11-*cis* retinal, closely resembling that reported here. The torsional angles of the chain are predicted by Honig and Karplus, and these parameters effectively define the shape of the molecule. Their torsional angles are all within 11° of our experimental values.

with the six-membered ring inclined to the plane of the chain. The inclination is given by the torsional angle of the 5-6-7-8 segment which measures 59° (the torsion angle of a planar *trans* conformation is 180°, and of a planar *cis* conformation is 0°; torsional angles are defined in ref. 12). This arrangement is typical of carotenoids, and the *trans* isomer does not differ significantly in any details from previously reported *trans* carotenoids[13].

The *cis* isomer is similar to the *trans* at the ring-chain junction; the ring torsion measured at atoms 5, 6, 7, and 8 is 40°. The chain segment from atoms 6 to 13 is essentially planar; this is contrary to the theoretical predictions mentioned earlier. The proposed models were nonplanar in this region, with torsions at the 10–11 or the 11–12 bonds ranging from 10 to 50°. The X-ray analysis indicates rotations from planarity of 8°, 4°, 0°, and 3° at the 8–9, 9–10, 10–11, and 11–12 bonds, respectively. The planar environment at the 10–11 bond corroborates a prediction of Patel[14], based on NMR observations. There is, however, an unexpectedly large torsion at the 12–13 bond, so that the atoms from C(12) to the terminal oxygen define a distinctly separate planar segment. The torsion at bond 12–13 is 39° from an s-*cis* conformation; therefore, the planar segments attached to this bond are rotated 141° from the *trans* conformation. As a result, the C(13)=C(14) and the C(15)=O double bonds are no longer parallel to the conjugated double bonds of the other segment. The best planar representation (structural formula) for this configuration is illustrated in Fig. 2, which also presents the bond distances of the two isomers. The corresponding bond distances of the chain are similar for the two isomers, even near the bend in the chain.



trans retinal

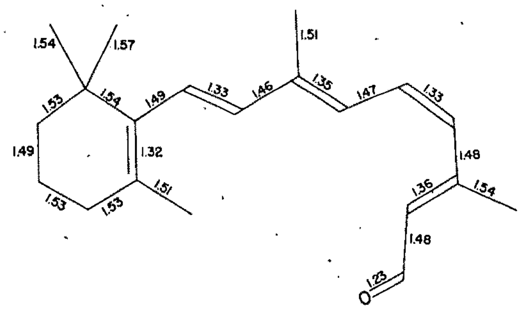


11-*cis* retinal

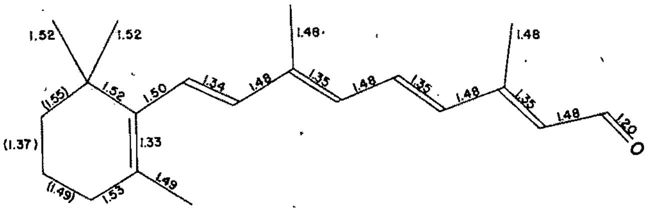
Fig. 1 Structures of the two retinal isomers. The ellipsoids drawn at each atom position indicate the relative magnitudes of the apparent thermal vibration amplitudes of the atoms. The solid black bonds represent the double bonds of the molecules.

Distortion of the bond angles of the *cis* retinal chain was noted at three points. The bond angles at atoms 11, 12, and 13 are 127.3, 130.3, and 120.6° in the *cis* isomer; the respective angles in the *trans* isomer are 121.6, 124.5, and 116.6°. The *cis* retinal has two short intramolecular approaches: atom 10 is 3.18 A from atom 13, and 3.23 A from atom 14. These atoms would approach more closely, and presumably would repel one another strongly, if the *cis* isomer were constrained to the bond angles characteristic of the *trans* isomer. Such a constraint is normally assumed in theoretical molecular folding calculations.

The problem of the conformation of the 11-*cis* retinal in solution remains. Large changes with temperature in the ultraviolet spectrum suggest an equilibrium involving more than one form of retinal. Torsions about the 10–11 and/or 12–13 bonds were discussed previously[15] to explain the spectral data. At that time, torsions about the 10–11 bond were preferred. One of us (W. S.) has since examined additional spectroscopic evidence, and now considers two conformations, differing by a large torsion about the 12–13 bond, to be the most probable forms in solution, with the s-*trans* form prevailing at lower temperatures (77 K).

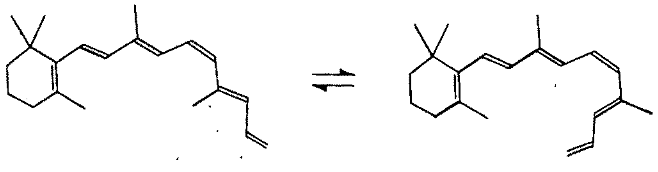


11-*cis* retinal



trans retinal

Fig. 2 Bond distances for the two retinal isomers. The planar chain of the *trans* isomer is drawn to scale and displays a slight curvature; this has been noted in other reports on carotenoid structures[13]. The bond distances in the ring of *trans*-retinal, which are enclosed in parentheses, represent the average values of a disorder. A ring puckering disorder was noted in canthaxanthin[13] in the C_2–C_3 region, and a similar disorder is indicated for the *trans* isomer.



s-*trans* s-*cis*

The labels s-*trans* and s-*cis* are approximate; in each case, twists away from these planar forms would be expected. A more detailed report on the spectroscopy of the retinals will be published elsewhere.

This research was supported in part by a grant from the US National Institutes of Health to D. G. McConnell of the Ohio State University. We gratefully acknowledge the assistance of Ch. N. Rafferty in preparing the 11-*cis* retinal crystals.

Optical Activity of LSD–DNA Mixtures

REPORTS on the fluorescence-sensitive binding of d-LSD (d-lysergic acid diethylamide), l-LSD and their 2-bromo derivatives to calf thymus DNA[1], and on changes induced in DNA circular dichroism by LDS-25 (ref. 2), have led to the belief that it is the intercalation of the drug in DNA that causes the chromosomal damage[3-6] and abnormalities in human offspring[7] that have been associated with LSD. Our studies of circular dichroism, however, have failed to show that LSD has any effect on DNA conformation.

To begin with, the circular dichroism (CD) of d-LSD, l-LSD and d-2-bromo-LSD at high concentrations does not conform with Beer's law: at concentrations greater than 0.02 mg/ml., for example, the CD bands in the region 260–290 nm are suppressed; at 0.1 mg/ml., the same bands reappear with inversion of the 220 nm band. These variations have not been explained but it is unlikely that at such high concentrations they are biologically relevant. As a consequence of this unexplained behaviour of LSD, we restricted our *in vitro* studies to solutions of DNA and LSD in which the LSD concentrations were less than 0.01 mg/ml., concentrations at which the results were reproducible and at which the Beer's law dependence of their spectra is verifiable.

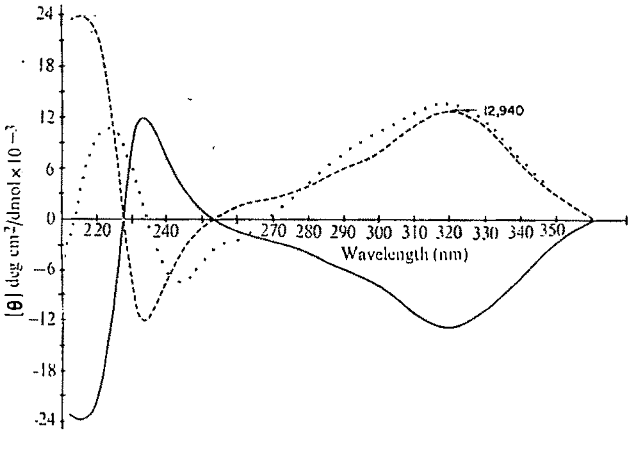

Fig. 1 The circular dichroism of l-LSD (——), d-LSD (- - -) and d-2-bromo-LSD (. . .). CD was measured on a Cary 60 spectropolarimeter with circular dichroism attachment, standardized with an aqueous solution of d-10-camphorsulphionic acid (K and K Laboratories, Plainview, New York), giving $E_L - E_R = 2.20 \pm 0.05$ at 290 nm. Solutions at *p*H 7.0 and 25° C in 0.02 M K_2HPO_4 gave the same spectra with both 0.01 M Tris (hydroxymethyl)aminomethane and 0.15 M NaCl. d-LSD, l-LSD and d-2-bromo-LSD are supplied in an L(+) tartrate buffer at 0.12 mM. Measurements were made at four different concentrations of LSD (maximum 0.01 mg/ml.) to verify conformity with Beer's law (see text). The LSD : tartrate ratio is constant for all of these studies[2,6]. Over the spectral region 215–370 nm L(+) tartrate does not contribute asymmetrically to the optical activity of d-LSD and l-LSD in the conditions studied. In all studies reported here, the l-LSD used was found to be the optical mirror of the d-LSD, as shown in the figure.

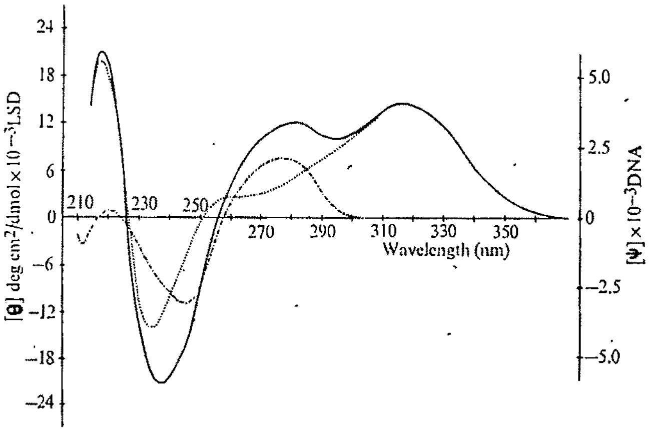

Fig. 2 The circular dichroism spectra of d-LSD (. . . .), DNA (.-.-.-) and their combination (——). The combination is a simple summation of the component spectra. The summed curves are the same in 10–50 mM Tris, 20–50 mM K_2HPO_4 and 100–150 mM NaCl at *p*H 6.5, 7.0 and 8.0. These are the conditions used by Wagner. DNA solutions were measured at concentrations of 20, 30, 60, 75, and 120 μg/ml.; the spectra with added LSD were always the sum of the component spectra. These particular curves were copied from spectra measured on a DNA solution at 20 μg/ml. d-LSD at 3.3×10^{-5} M. Spectra were measured at room temperature. Calf thymus DNA was purchased from Sigma Chemical Co., St Louis, Mo. Other DNA was supplied by Professors Antero So and Sheldon Greer whose DNA (*B. subtilis*) was shown, apart from physical measurements, to possess full biological activity; the biological activity and integrity of the DNA were determined by assaying the capacity of low concentrations of DNA to transform two genetic markers (*his* 31 and *ind* 168) that are linked to the extent of 65%.

In previous work on this subject, the purity of the LSD sample with respect to isomeric forms was not determined. Some have used a racemic mixture (Wagner, private communication). To ensure that our comparisons between d-LSD and l-LSD are valid, solutions were used which gave mirror-image CD spectra of the particular isomer that was used in each case (Fig. 1). Solutions of each isomer are then pure or at worst slightly cross-contaminated to the same degree by the other enantiomer, because they also give characteristic rotations at the sodium D line.

Studying the circular dichroism of DNA in the presence of d-LSD (the psychotomimetic congener) we found no significant changes; the changes were less than 1% of those reported by Wagner[2] in the same conditions; the interaction of d-LSD and DNA, shown by the fluorescence quenching experiments of Yielding and Sterglanz, did not cause any conformational change in either the d-LSD or DNA. In the spectral region 400–200 nm, the circular dichroism of the d-LSD–DNA complex results simply from a combination of the individual d-LSD and DNA spectra (Fig. 2). The calculated LSD+DNA and observed spectra are identical. The DNA was considered to be "native" when they gave CD spectra of native DNA, as defined by Brahms and Mommaerts[8]. The absence of any new optically active contribution to the DNA circular dichroism, when d-LSD was present in the DNA solution, was verified in three different solutions, 0.15 M NaCl, 0.01 M Tris and 0.02 M K_2HPO_4, each at *p*H 6.5, 7.0 and 8.0. Additional annealing of the DNA to close the small open stranded regions and to correct mismatched base-pairing by warming to 50, 60 or 67° C and slow cooling produced no changes in the ability of d-LSD to "intercalate" with DNA, that is, it produced no changes in optical activity other than those associated with the LSD and DNA themselves. This was true whether the DNA was heated in the presence or absence of any of the LSD forms. Furthermore, DNA from *Bacillus subtilis*, *Escherichia coli*, bovine spleen, sheep bone marrow and phage T4 gave the same negative results, showing the absence of any interaction for a wide range of $(A+T)/(C+G)$ ratios.

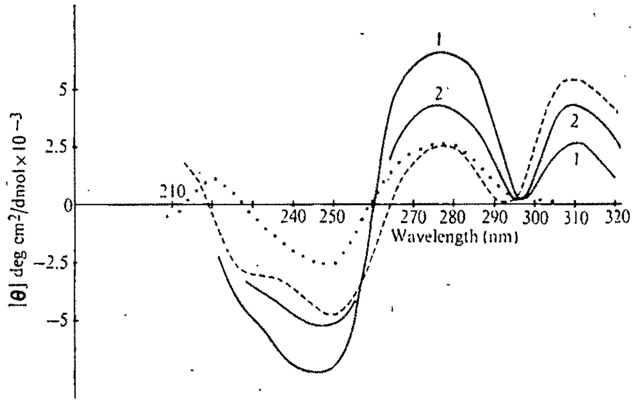

Fig. 3 The CD spectra of ethidium bromide–DNA mixtures. . . ., Curve represents pure calf thymus DNA. The differences in intensities between curves 1, 2 and the broken line relate to the age of the DNA solution. Curve 1 describes the freshest DNA solution; curve 2 was obtained from solutions that had been stored at 4° C for a week, and the dashed curve represents a much older solution of DNA, about 4 weeks old. One can obtain the dashed curve on a freshly prepared solution of old DNA which has been stored as a cold dry powder. The dashed curve is closest to the one published by Wagner[2]. Several samples of calf thymus DNA (Sigma) gave even higher ellipticity values at 272 nm with ethidium bromide, and it may be that they were the most "native" of the more than thirty preparations tested, but the curves reported here are the three which proved to be characteristic of three reproducibly different states of DNA. In spite of the variation in ethidium bromide-induced changes, the DNA alone always gave the same CD spectrum. In all cases the concentration of DNA is 30 μg/ml. and the concentration of ethidium bromide is 3.3×10^{-5} M. The more intense spectra were most consistent for solutions in 10 mM Tris, as compared with phosphate and NaCl solutions.

To eliminate artefacts arising from nicking of the DNA during handling as a complicating factor, experiments were done in two ways: in the first, solutions of fresh DNA were gently poured; and in the second, DNA solutions were extruded through hypodermic syringes with small bore needles. But, in spite of the different degrees of shearing, the results of the two were identical; in both cases, the circular dichroism of the LSD–DNA solution was the sum of the individual LSD and DNA spectra.

The fluorescence changes seen by Yielding and Sterglanz on the binding of LSD to DNA indicated to them that the sort of interaction which occurs is a "general property of this group of drugs", and that the "binding ratio was one drug molecule per base moiety in the DNA chain". It would seem, therefore, that while the drugs of this group may interact with DNA in such a way that their fluorescence emission is suppressed, circular dichroism indicates no conformational change, certainly none similar to that observed in DNA in the presence of the trypanocidal dyes, ethidium bromide or isometamidium chloride. In this respect we are in agreement with Yielding and Sterglanz: the behaviour of dn, ln and d-2-bromo-LSD in the presence of DNA is the same, regardless of the form of LSD.

The CD of ethidium bromide–DNA combinations is shown in Fig. 3. Since ethidium bromide is a good example of the planar compounds believed to intercalate with DNA[9–11], its effect on DNA circular dichroism serves as a useful basis for comparison in assessing the possible effects of LSD. We found, for example, that the character of the ethidium bromide-induced optical activity is influenced considerably by the age of the DNA solution (Fig. 3).

There is no similarity in behaviour between the LSD–DNA solutions (Fig. 2) and the ethidium bromide–DNA complexes (Fig. 3) and it is unlikely therefore that LSD forms this type of complex with DNA. For example, a significant reciprocal behaviour in ellipticity was found (Fig. 3) in the ethidium bromide–DNA interaction between the positive band at 272 nm, which arises from ethidium bromide. It was also observed by Aktipis and Martz[9–11] and it is in accord with Tinoco's[12] general theory of optical activity. It is evidence for a strong interaction between ethidium bromide and DNA which in no way resembles that between DNA and LSD in any of its forms.

We have also studied the CD spectra of combinations of LSD forms with whole tRNA and pure tryptophanyl-$tRNA_{trp}$ of *E. coli*. No additional optical activity was generated beyond the contributions of tRNA and LSD measured singly, and neither d-LSD nor l-LSD affected the capacity of $tRNA_{trp}$ to charge tryptophan.

Recently, it was reported[13] that LSD does not damage chromosomes of *E. coli* except at very high concentrations and high ultraviolet light intensity. Unfortunately, the isometric purity of the LSD used in this work was not determined and a maleate salt of LSD was used whereas others have generally used an L(+)tartrate salt. We emphasize the importance of measuring the relative concentrations of the dn and ln forms and of a uniformity in the preparations used. The conflicting results of studies of LSD-induced chromosomal damage[14] may be largely attributable to differences in isomer concentrations and buffering agents in the LSD preparations. Furthermore, some early LSD–DNA spectra seem to be inaccurate, and do not provide a firm basis for consideration of the mode of action of LSD.

We thank Professors Robert G. Heath and Robert J. Boucek for encouragement and assistance and Dr John A. Scigliano for supplying the LSD for these studies. The work was supported in part by grants from the National Institutes of Health, the US Public Health Service, the Florida Heart Association and the Programme Project Grant.

LSD-25 Does Not Intercalate in DNA

APART from its hallucinogenic effect, lysergic acid diethylamide (LSD-25) is believed to cause chromosome abnormalities[1-3], which have been attributed to a direct interaction of the LSD-25 and DNA[4]. The apparent resemblance of the circular dichroism spectra of the DNA–ethidium-bromide complex and mixtures of LSD-25 and DNA has led to the suggestion that LSD-25 might be intercalated in the DNA[5].

A more specific and sensitive method for studying intercalation is provided by the interaction of drugs with twisted, circular, covalently closed duplex DNA[6-8]. By intercalating molecules into the DNA the duplex is unwound and, because the total number of duplex turns and supertwists is a topological invariant, this leads to the unwinding of the supertwists and therefore to the conversion of twisted circles into open circles[9]. This change in form can be followed by sedimentation analysis, or, more conveniently, in a viscometer[15]. We have used this method to verify Wagner's suggestion[5] that LSD-25 intercalates.

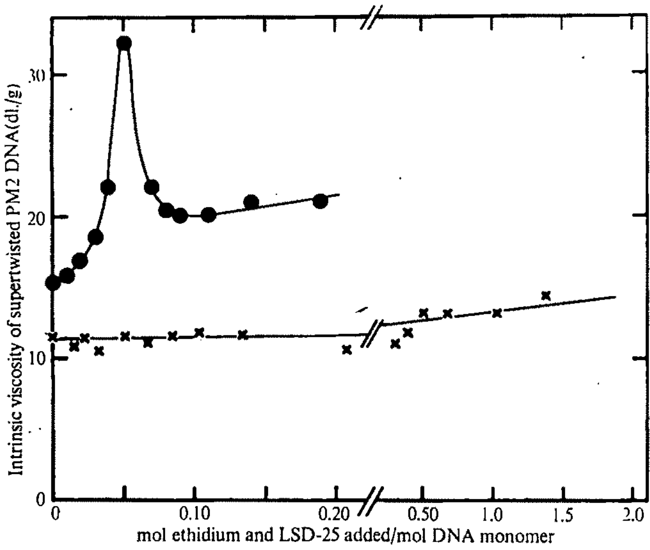

Fig. 1 The intrinsic viscosities of the DNA from phage PM2 as a function of the ethidium (●) and the LSD-25 (×) concentration present. Conditions were: temperature 20° C; DNA concentration, 27 μg ml.$^{-1}$ of 15 mM NaCl, 1.5 mM sodium citrate, *p*H 7.0 (●), and 20.3 μg ml.$^{-1}$ of 10 mM sodium phosphate, *p*H 7.0 (×). The intrinsic viscosities were determined in a rotating cylinder viscometer (Krannich GMbH, Göttingen) according to Zimm and Crothers[10]. Ethidium was a gift from Boots, and LSD-25 was purchased from Sandoz.

Fig. 1 shows the results of an experiment in which we compared the effect of LSD-25 and the intercalating dye ethidium on the closed circular duplex DNA of bacteriophage PM2 (refs. 11 and 12). Whereas the results with ethidium were as expected, no interaction between DNA and LSD-25 was detectable, in the range of concentrations in which strong interaction was found by others[4,5].

We therefore repeated previous experiments, in which interaction between LSD-25 and DNA was detected spectrophotometrically. In contrast to the results of Yielding and Sterglanz[4], the spectra of different mixtures of LSD-25 and DNA between 220 and 600 nm were the exact summations of the two components separately; in contrast to Wagner's results[5], we also found complete additivity for the circular dichroism spectra.

These results indicated that either LSD-25 does not interact directly with DNA, or that our LSD sample contained no LSD-25. The latter alternative was excluded by infrared spectroscopy and NMR studies. We therefore conclude that chromosome damage in the presence of LSD-25 is not a consequence of the intercalation of LSD-25 into DNA.

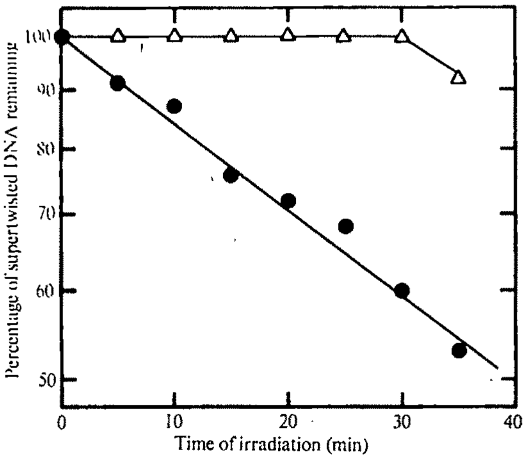

Fig. 2 Breakage of the supertwisted from of PM2 DNA by ultraviolet irradiation in the presence of LSD-25. Samples were irradiated with (●) and without LSD-25 (△) with a germicidal lamp. The radiation below 300 nm was cut off by a glass filter. Conditions were: DNA concentration, 63.5 μg ml.$^{-1}$; LSD-25 concentration, 310 μM; medium 15 mM NaCl + 1.5 mM sodium citrate, *p*H 7.0. The conversion of the supertwisted PM2 DNA was followed by band sedimentation of small samples through neutral 3 M CsCl in an MSE analytical ultracentrifuge. The percentage of supertwisted DNA was estimated from scannings at 260 nm, using a Dupont 310 curve resolver.

During these experiments, we noted that irradiation of DNA with ultraviolet light in the presence of LSD-25 led to phosphodiester bond breakage, even if most of the radiation below 300 nm was cut off with a glass filter. This phenomenon was illustrated by the experiment in which phosphodiester bond breakage in DNA was measured by the conversion of the closed circular duplex form of PM2 DNA to slower sedimenting material (Fig. 2). Electron microscopy confirmed that the irradiation led to the formation of open circles rather than linear molecules. There was no conversion when DNA was irradiated in the absence of LSD-25 or when DNA–LSD mixtures were kept in the dark. Although the conditions used in this experiment were very different from those prevailing *in vivo*, it should be realized that the molecular weight of PM2 DNA is only 6×10^6, whereas a human diploid nucleus contains 4×10^{12} daltons of DNA[13]. LSD-25-dependent photo-destruction of DNA could therefore contribute to chromosome damage in tissue culture experiments and possibly *in vivo*, and photo-sensibilization of an *Escherichia coli* mutant, deficient in repair, by high concentrations of LSD-25 has been reported[14].

We thank Dr B. F. van Gelder for discussions and Mr C. Kruk, Mrs F. Fase-Fowler, Mr W. de Jong, Mr G. Pauw and Miss J. E. de Boer for assistance. A Cary 60 instrument with a 6002 CD attachment was purchased from funds from the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organization for the Advancement of Pure Research (ZWO).

Induced Optical Activity of 2,4-Dinitrophenyl-lysine Specifically Bound to Mouse MOPC-315 Myeloma Protein

THE optical activity generated by the interaction of small ligands with proteins, visible as extrinsic optical rotatory dispersion (ORD) Cotton effects or circular dichroism (CD) bands, has been used extensively to study the binding of ligands to non-antibody proteins[1,2]. We describe here the use of circular dichroism to monitor the binding of DNP-lysine to a mouse IgA myeloma protein with high affinity for dinitrophenylated haptens[3-5].

The MOPC-315 mouse tumour line of Potter and Lieberman[6] was maintained in 5–8 month old BALB/c mice, and the IgA myeloma protein was purified from ascitic fluid by affinity chromatography[5]. DNP-lysine (ε-N-2,4-dinitrophenyl-L-lysine)-'Sepharose' was prepared by the method of Porath, Axen and Ernback[7]. We washed a 10 ml. DNP-'Sepharose' column with 200 ml. of 0.15 M NaCl–50 mM sodium borate buffer (*p*H 8.4), 10 ml. of 1% (w/v) bovine serum albumin, 200 ml. of 1 M acetic acid and 200 ml. of borate-buffered saline immediately before use. MOPC-315 ascitic fluid was dialysed against borate-buffered saline, and the protein was reduced at 25° C with 10 mM dithiothreitol for 1 h, and alkylated for 30 min at 4° C with a 10% molar excess of iodoacetamide. The reduced and alkylated protein was dialysed against borate-buffered saline and applied to a DNP-'Sepharose' column, which was washed with the same solvent, and the MOPC-315 myeloma protein was eluted with 1 M acetic acid. The recovered protein was immediately dialysed against borate-buffered saline (*p*H 8.4) at 4° C, and insoluble materials were removed by centrifugation. Examination of the purified protein by immunoelectrophoresis with rabbit anti-mouse serum and anti-MOPC-315 protein sera yielded only a single component.

Circular dichroism was measured at 25° C with a JASCO ORD/UV-5 spectropolarimeter equipped with a CD attachment, and standardized with d-camphor-10-sulphonic acid. Cell path lengths of from 1.0 cm to 0.1 mm, and protein concentrations between 0.8 and 4×10^{-3} g per 100 ml., were used to determine the CD spectrum (600 to 200 nm) of the MOPC-315 protein. The data are given in molar ellipticities, $[\theta]_\lambda$, in degrees cm^2 dmol^{-1}, where $[\theta]_\lambda = \frac{3{,}300}{lc}(A_L - A_R)_\lambda$, and l = the path length (cm), c = the molar concentration and $(A_L - A_R)_\lambda$ is the observed difference in absorption between left and right circularly polarized light at wavelength λ. The average residue weight, M_0, taken as 110 (rather than the molecular weight) for the MOPC-315 protein was used to obtain the protein $[\theta]_\lambda$ values. We determined optical density difference spectra with a JASCO ORD/UV-5 spectrophotometer. The quenching of MOPC-315 protein fluorescence by DNP-lysine (Sigma)[3] was measured with a Zeiss double M4 QIII monochromator spectrofluorometer with a Farnell stabilized EHT power supply and a Keithley 610 B electrometer, in a thermostatically controlled cell compartment at 25° C. The data were corrected for dilution and internal quenching as before[8]. Protein concentrations were determined from the optical density at 280 nm (corrected for light scattering), measured with a Zeiss PMQII spectrophotometer, with an extinction coefficient, $E_{1\ \mathrm{cm}}^{1\ \mathrm{mg\ ml.}^{-1}}$, of 1.44 for the MOPC-315 IgA protein[3,5]. The molar extinction coefficient, ε, at 362 nm for DNP-lysine was taken as 1.75×10^4 (ref. 5).

The CD spectrum of the MOPC-315 protein is shown in Fig. 1*A*. No circular dichroism was evident in the protein spectrum from 600 to 315 nm. DNP-lysine (up to 1.3×10^{-4} M) in free solution, and in the presence of immunoglobulins lacking DNP-specificity, also had no optical activity in this wavelength range (Fig. 1*B*). In contrast, binding of the DNP-lysine ligand by the MOPC-315 protein generated distinct circular dichroism bands (Fig. 1*B*). A broad positive band centred near 410–420 nm, a sharper positive band at 380 nm and a broad negative band extending from 360 nm to 270 nm and centred near 295 ± 15 nm were observed in the CD spectrum of the MOPC-315–DNP-lysine complex (Fig. 1*A* and *B*). The absorption spectra of DNP-lysine in free solution, and DNP-lysine specifically bound to the MOPC-315 protein, are also recorded in Fig. 1*B*. The redshift and hypochromicity[3] were evident after complexing the ligand with the myeloma protein, the absorption maximum being shifted from 362 nm for free DNP-lysine ($\varepsilon = 1.75 \times 10^4$) to 368 nm for bound DNP-lysine ($\varepsilon = 1.52 \times 10^4$).

Hapten-binding curves were constructed by serially adding DNP-lysine (with a Hamilton microsyringe) to a constant amount of MOPC-315 protein, and measuring the circular dichroism at 325 nm and 380 nm. The $(A_L - A_R)_{325\ \mathrm{nm}}$ data (uncorrected for dilution) have been plotted as a function of the total DNP-lysine concentration (Fig. 1*C*). The mean value for $(A_L - A_R)_{325\ \mathrm{nm}}$ at saturation (that is $(A_L - A_R)_{\max}$ at DNP-lysine concentrations greater than 8×10^{-5} M), corrected for dilution, was 5.32×10^{-4}. The $(A_L - A_R)_{325\ \mathrm{nm}}$ values were divided by the total DNP-lysine concentration to give the apparent value of $[\theta]_{325\ \mathrm{nm}}$, and these values are also plotted in Fig. 1*C* as a function of the total DNP-lysine concentration. The mean of the maximum values for $[\theta]_{325\ \mathrm{nm}}$ (apparent) (total DNP-lysine concentration less than 6×10^{-5} M) gave $[\theta]_{325\ \mathrm{nm}}$ as -2.10×10^4 degrees cm^2 dmol^{-1}. Similarly, $[\theta]_{380\ \mathrm{nm}}$ was calculated to be 1.68×10^4 degrees cm^2 dmol^{-1}. The molar concentration of antibody combining sites was determined from the ratio $((A_L - A_R)_{\max}/[\theta]_{325\ \mathrm{nm}})$ to be 1.71 mol of sites per 153,000 g of protein.

The intrinsic association constant is an additional parameter for evaluating $[\theta]_\lambda$. The association constant, K_A, obtained for the MOPC-315 protein from the fluorescence quenching data (Fig. 1*D*) was 0.6×10^7 mol^{-1}, consistent with the value reported by Eisen, Simms and Potter[3]. The association constant, $K_A = \frac{r}{(n-r)c'}$, where r is the number of moles of hapten bound per mol of bivalent antibody, $n = 2$, and c' is the free hapten concentration[3,8]. The value of r at each dilution may be obtained from the observed $(A_L - A_R)$ values, corrected for dilution, as the ratio $(2(A_L - A_R)$ observed$/(A_L - A_R)_{\max})$. At $r = 1$, $c' = \frac{1}{K_A}$, $c = [(\text{total DNP-lysine concentration}) - c']$. and $[\theta]_\lambda = \frac{3{,}300}{cl}[(A_L - A_R)_\lambda$ at $r = 1]$. The values for $[\theta]_{325\ \mathrm{nm}}$ and $[\theta]_{380\ \mathrm{nm}}$ calculated by this procedure were -2.13×10^4 and 1.66×10^4 degrees cm^2 dmol^{-1}, respectively, consistent with the values we obtained from the $[\theta]_\lambda$ (apparent) against total DNP-lysine concentration plots (Fig. 1*C*).

For lower affinity antibodies ($K_0 \sim 10^5$ mol^{-1}), circular dichroism is an alternative method to determine directly the association constant.

The optical activity of the inherently symmetric DNP-chromophore is generated by the interaction of the DNP group with asymmetrically placed vicinal groups in the antibody combining site of the MOPC-315 protein. The reciprocal relationship of the positive and negative CD bands, together with the large molar extinction coefficient of the DNP group, suggests that the optical activity of the DNP-lysine–MOPC-315 protein complex results (at least partly) from dynamic coupling of electronic transitions of the DNP group and a protein chromophore (for example, tryptophan or tyrosine) in the antibody combining site[2,9,10]. Little and Eisen[11] have studied the difference spectra resulting from the association of DNP ligands and TNP ligands with antibody, and suggested that a tryptophan residue is present in the combining sites of anti-DNP and anti-TNP antibodies, from several sources. Circular dichroism presents a further experimental parameter with which to explore this possibility. The magnitude of the rotational strength of reciprocal CD bands depends on the relative orientation of the transition dipole moment vectors of the interacting chromophores[2,10]. Circular dichroism bands which result principally from vicinal perturbations static in nature (for example, asymmetric distribution of charge on vicinal groups), are also sensitive to the relative orientation of the ligand and the amino-acid residues in the antibody combining site. Circular

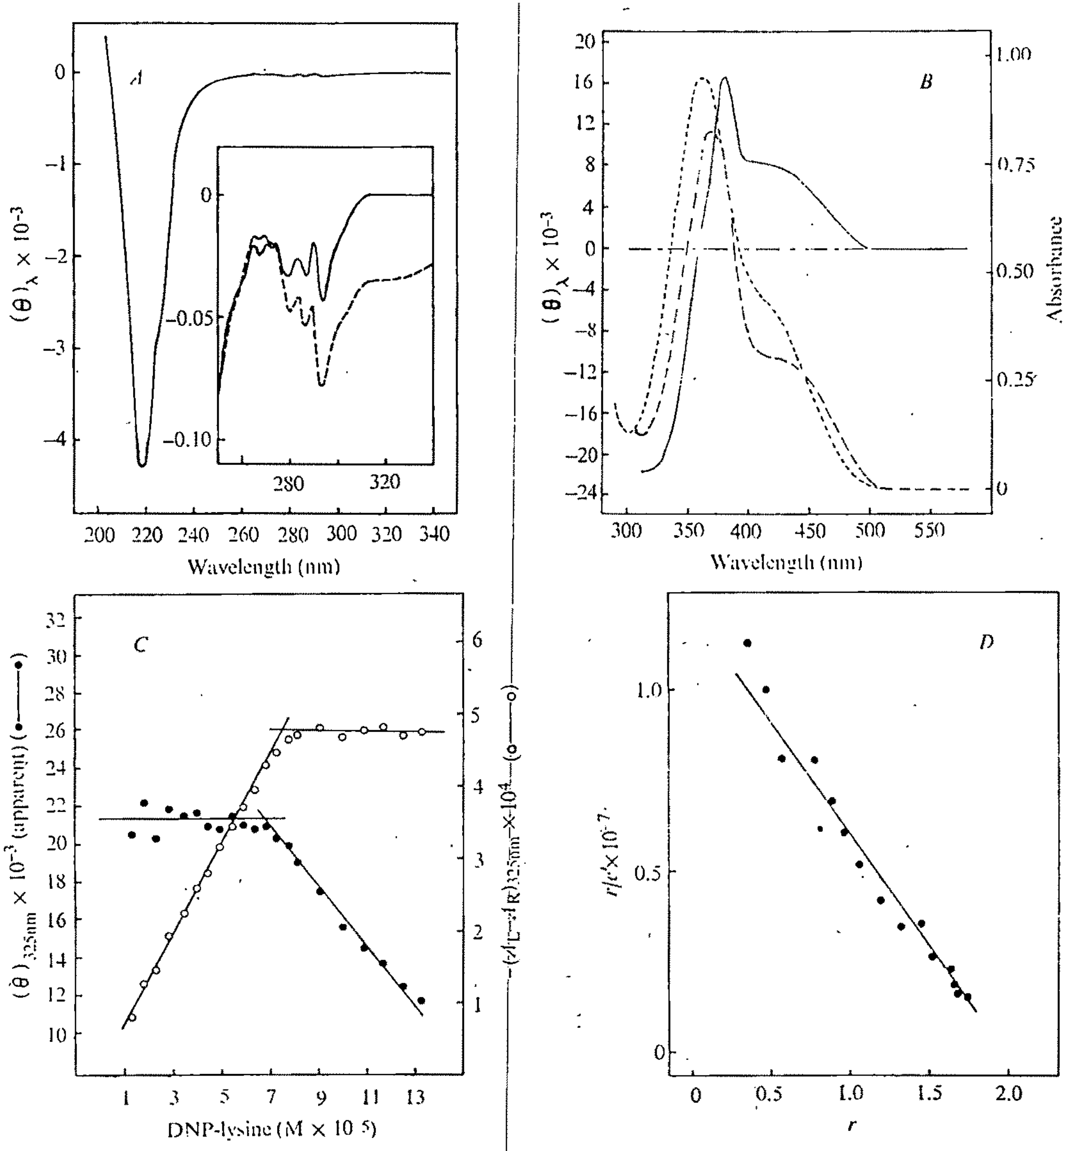

Fig. 1 *A*, Circular dichroism spectrum of MOPC-315 IgA myeloma protein in 0.1 M NaCl–10 mM sodium phosphate buffer (*p*H 7.2), or 0.1 M NaCl. The inset illustrates the aromatic region with an expanded $[\theta]_\lambda$ scale (———). The circular dichroism spectrum of the DNP-lysine–MOPC-315 protein complex in the protein aromatic amino-acid absorption region is also illustrated in the inset (– – –). DNP-lysine in free solution showed no circular dichroism from 600 to 220 nm. *B*, Circular dichroism spectrum of ε-N-2,4-dinitrophenyl-L-lysine in free solution in 0.15 M NaCl–50 mM sodium borate buffer (*p*H 8.4) (— — —), and bound to the MOPC-315 IgA myeloma protein (———). The $[\theta]_\lambda$ values below 315 nm have been corrected for the CD contribution from the protein alone. The absorption spectrum of DNP-lysine (- - -) and an equal molar concentration of DNP-lysine bound to the MOPC-315 protein (— — —) are also shown. The same concentration of MOPC-315 protein without DNP-lysine was used as a reference to obtain the difference spectrum of DNP-lysine bound to protein. The DNP-lysine–MOPC-315 difference spectrum was examined at $r=1.2$ where more than 99% of the total DNP-lysine present was specifically bound to protein. *C*, Hapten binding curves constructed by serially adding 10–20 µl. of 1.07 mM DNP-lysine to 14.8 mg of MOPC-315 protein in 2.0 ml. of 0.15 M NaCl–50 mM sodium borate buffer (*p*H 8.4). The $(A_L-A_R)_{325\,nm}$ data, uncorrected for dilution, have been plotted as a function of the total DNP-lysine concentration (○). The values of $[\theta]_{325\,nm}$ (apparent) $= \frac{3{,}300}{l}\,[(A_L-A_R)/(\text{total DNP-lysine concentration})]$ have also been plotted as a function of the DNP-lysine concentration (●). *D*, DNP-lysine hapten binding data for the MOPC-315 protein of *C*, obtained by fluorescence quenching. Data are plotted in terms of *r* and *c′*, where *r* is the number of moles of hapten bound per mol of bivalent antibody, and *c′* is the free DNP-lysine concentration. The molar concentration of antibody combining sites ($n=2$) was determined from the CD binding data (see text).

dichroism, therefore, is a powerful method for the study and comparison of the fine structure of the antibody combining site.

Localization of A Antigen Sites on Human Erythrocyte Ghosts

DETAILED immunochemical knowledge of the heterosaccharide antigen determinants of the ABO blood groups has been gained from the study of glycoproteins of mammalian secretions[1-3]. Less is known about the chemical composition and spatial distribution of the ABO antigen determinants in erythrocyte membranes. Because the erythrocytes envelope appears as a uniform unit membrane after positive staining[4], standard electron microscopy has failed to relate the ABO antigen sites to any discrete membrane structure[5].

We have demonstrated a new method for the study of the topochemistry of membrane surfaces[6] which utilizes freeze-etching, a technique involving fracture, which splits the membrane and exposes its inner, hydrophobic matrix[6,7] (Fig. 1, left), followed by etching, which exposes the membrane surface by lowering the ice table[6,8] (Fig. 1, right).

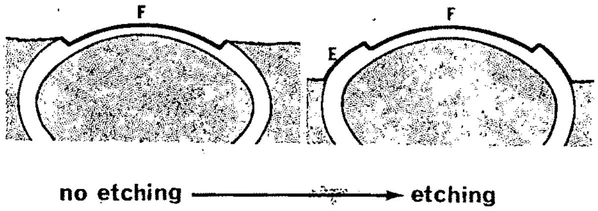

Fig. 1 Faces exposed by freeze-etching red blood cell ghosts: fracture splits the membrane (fracture face, *F*); subsequent etching lowers the ice table and exposes the membrane surface (etched surface, *E*). Because the membrane is split, there is a step or ridge between the fracture face and the etched surface.

In the erythrocyte membrane, the hydrophobic matrix exposed by the fracture process, is structurally differentiated into smooth areas and particles[9,10]. The particles average 85 Å in diameter (uncorrected for shadow thickness) and seem to protrude to the membrane surface[9]. Their chemical nature is unknown, although indirect evidence suggests that they are proteins[9,11-14]. We show here that the A antigen sites of the human erythrocyte ghost are associated with these membrane particles.

Human erythrocyte ghosts from blood group A_1, and controls from blood group O, were prepared[15] from fresh whole blood drawn in acid citrate dextrose buffer. Immune anti-A (Hyland Division, Travenol Laboratories, Los Angeles) was fractionated by chromatography on DEAE cellulose, and the IgG fractions (eluted with 0.01 M phosphate buffer, *p*H 8.0) were pooled and concentrated by ultrafiltration. The A antigen sites were labelled indirectly with ferritin conjugated to the IgG fraction of rabbit anti-human IgG[16]. A_1 or O ghosts (50 μl. of packed ghosts plus 50 μl. of 20 mM phosphate buffer, *p*H 7.5) were incubated for 75 min at room temperature, with 5 mg of the anti-A IgG fraction in a total volume of 8 ml. After washing three times with 100 volumes of the buffer, the cells were incubated at room temperature with 0.4 ml. of the conjugate for 150 min. The cells were centrifuged and resuspended in cold 20 mosmolar phosphate buffer containing 1 mM $MgCl_2$, sedimented, resuspended in a 1 : 10 dilution of the same buffer and then washed three times in distilled water. For freeze-etching, portions of the pellet were mounted on cardboard disks and quenched in chlorodifluoromethane ('Freon 22') cooled by liquid nitrogen. Specimens were fractured, etched for 1 min at −100° C and replicated in a Balzers apparatus[17].

Washing the ghosts in distilled water caused appreciable aggregation of almost all the membrane particles (Fig. 2)[9]. The patterns formed by these particle aggregates helped us to recognize their protrusions on the etched surface and enabled us to judge the location of the ferritin molecules relative to the membrane particles (Fig. 2*b* and *c*).

Extensive examination of the replicas showed that the ferritin-markers, and thus the anti-A antibodies, were consistently associated with the particle aggregates on the surfaces of A_1 erythrocyte ghosts (Fig. 2*b* and *c*). It could be argued, however, that the A antigen sites were not associated with the membrane particles, but that antigens and particles co-aggregated during washing. We thought this unlikely, because if the antigen sites were not associated with the membrane particles random co-aggregation should produce some particle-free antigen aggregates and, consequently, ferritin labelling on the smooth zones of the ghost membrane. We counted the ferritin molecules which corresponded to zones devoid of particles; in a survey of 121 of those smooth zones, only three ferritin molecules were found (there were 296 ferritin molecules on the remainder of the etched surfaces). Furthermore, in an analysis of the position of 1,500 ferritin molecules, only sixteen were not associated with any particle aggregates. Because no ferritin was observed on group O controls, we concluded that the binding of the ferritin was a specific antigen–antibody reaction which localized the A antigen sites on the membrane particles.

The number of marker molecules was much lower than the current estimates of the number of antigen sites of A_1 cells. Our experimental conditions were not chosen to optimize binding to a substantial proportion of the antigen sites, but to minimize agglutination which would make it impossible to expose the outer membrane surface by etching. Preliminary experiments to observe directly the anti-A antibody suggest that most membrane particles possess A antigen sites. This makes the agreement between the current estimates of the number of A antigen sites in A_1 cells ($8-11 \times 10^5$)[18] and the number of membrane particles in the human erythrocyte membrane (4,200 μm^{-2} or about 6.2×10^5 per erythrocyte)[9,11] interesting[19], but it may be coincidental.

Because the molecular species containing the A and B antigens in the human erythrocyte membrane are probably glycoprotein[20-22] and glycolipid[23,24], the correspondence between the antigen sites and the membrane particles implies

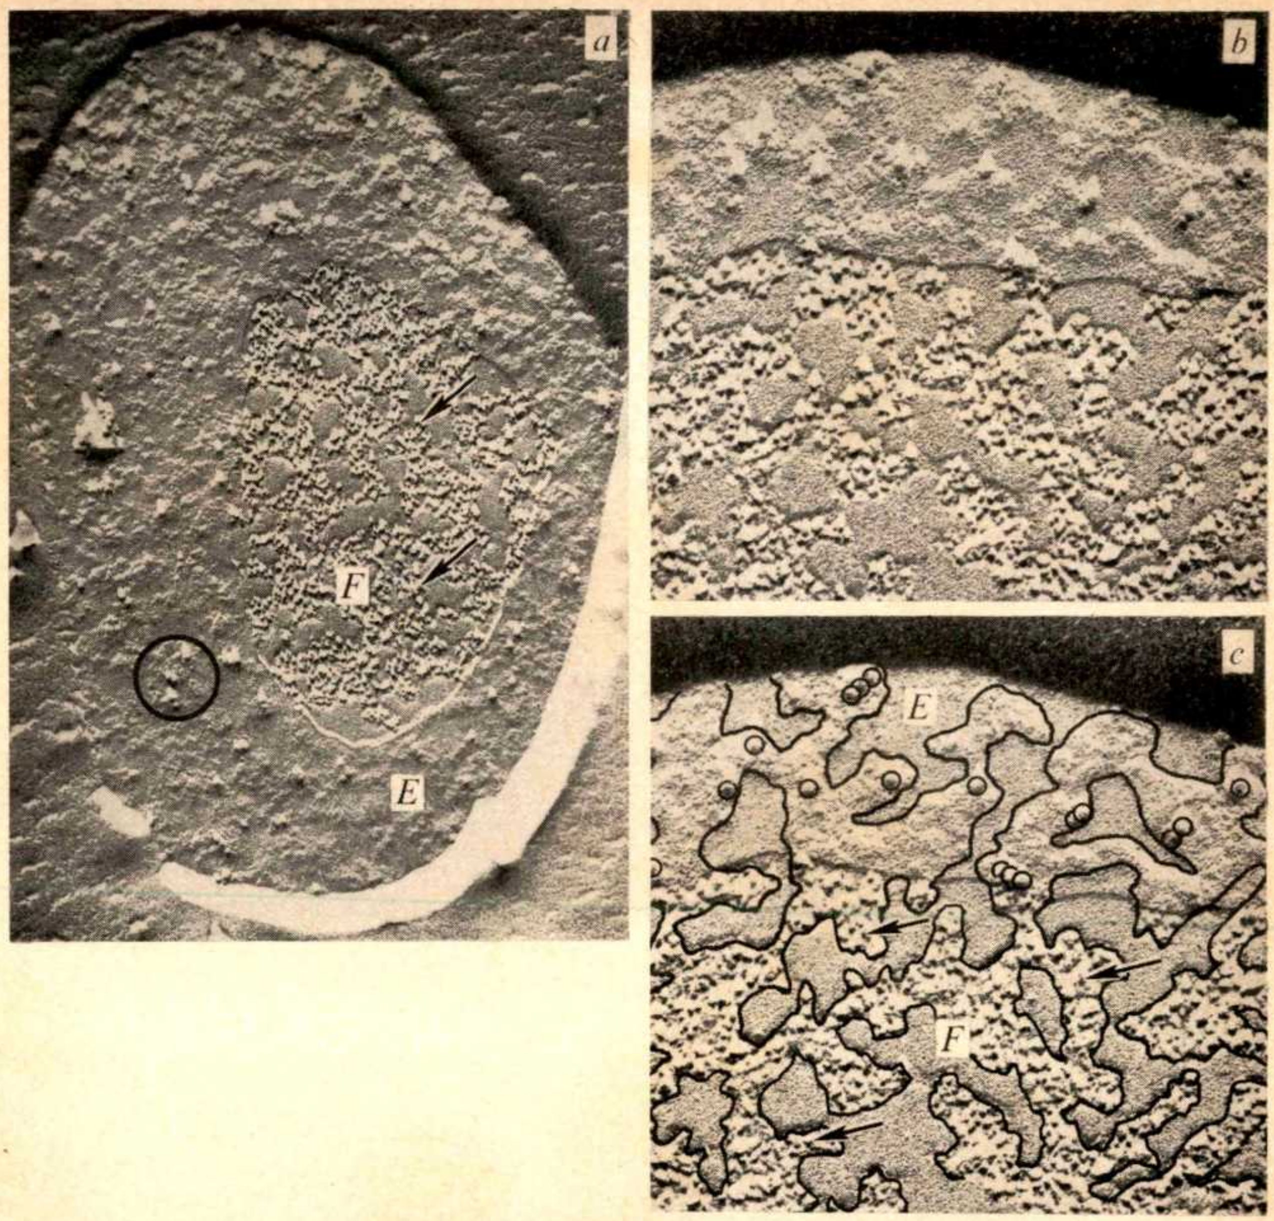

Fig. 2 Freeze-etched A_1 human erythrocyte ghosts labelled with ferritin conjugate indirectly bound to A antigen sites (*a*, 75,000; *b* and *c*, ×130,000). A ridge separates the fracture face (*F*) from the etched surface (*E*). Aggregates of membrane particles (arrows) are visible on the fracture faces and protrude to the etched surfaces where they appear as roughened zones (*b*, outlined and labelled in *c*); the outlines of the roughened zones on the etched surface are continuous with the outlines of the particle aggregates on the fracture face. Ferritin molecules (encircled, *a* and *c*), and therefore A antigen sites, are associated only with the protrusions of the membrane particles on the etched surface.

that the particles contain glycoprotein or glycolipid moieties. Although most of the membrane particles are preferentially associated with the inner half of the membrane[9,11], they must protrude to the outer surface where they carry the heterosaccharide ABO determinant. The particles probably have other functions; they seem to traverse the entire membrane, thus providing a structural pathway which may be important in transport phenomena. Extrapolating the present results to the native erythrocyte membrane should be viewed with caution, although preliminary experiments showed that there was no loss of haemagglutination titre in erythrocyte ghosts, either before or after washing in water.

The combination of immunochemical and freeze-etch techniques used here can be extended to study the relationship of membrane particles to other antigen systems, receptor sites, enzymes and transport functions in erythrocyte and other membranes.

We thank Drs Leon Wofsy, Anne Good, Hugh Fudenberg and Mrs Rose Bonhag for advice; Dr Herbert Perkins of the Irwin Memorial Blood Bank for blood samples; and Susan Whytock and Eleanor Crump for technical assistance. Treatment of Murine Leukaemia with Heterologous Antiserum or Cyclophosphamide

WE have compared chemotherapy and immunotherapy in AKR mice injected with a syngeneic tumour, strain BW5147 lymphatic leukaemia. Previous investigations disclosed significant therapeutic benefit from isologous or homologous antiserum against mouse leukaemia[1–4] or with antiserum raised against murine tumour viruses[5]. In contrast, toxicity has been a significant obstacle to the therapeutic use of heterologous antiserum[6,7]. Reports[8–12] of successful use of heterologous antiserum, however, suggested that further study was warranted, and an experiment was designed to compare quantitatively the therapeutic activity of antiserum with conventional chemotherapy.

Strain BW5147 leukaemia was invariably lethal for untreated AKR mice. Median survival time (MST) was 10.0±0.6 days after injection of 10^6 cells intraperitoneally in thirty-two passages utilizing 200 mice. Dispersed cell suspensions were prepared as described previously[13].

Cyclophosphamide ('Cytoxan') was selected for chemotherapy because of previous studies with L1210 leukaemia, in which a 10^{-3} (99.9%) reduction in tumour was achieved with 100 mg/kg[14]. Toxicity of cyclophosphamide in AKR mice was similar to toxicity in other mice[15], and LD_{50} in fifty AKR mice was 375 mg/kg.

Antitumour serum (ATuS) and antilymphocyte serum (ALS) were prepared by intravenous injections of tumour cells or normal AKR spleen and thymus cells in New Zealand rabbits. Serum was decomplemented and AKR red blood cell (RBC) absorption was performed until haemagglutination titre was negative. In four preliminary experiments, tumour-injected mice treated with RBC-absorbed ATuS had an increase in MST of 42–89% (ref. 16). MST was not prolonged by ALS or normal rabbit serum.

The effects of cyclophosphamide and RBC-absorbed ATuS were compared after injection of 10^6 BW5147 cells intraperitoneally. Single cyclophosphamide doses of 20, 40, 60, 80, 120 or 160 mg/kg were given. ATuS was administered in doses of 3.0 ml. once, 1.5 ml./day for 3 days, or 0.25 ml./day until death. Untreated control mice were injected intraperitoneally with serial ten-fold dilutions of tumour cells from 10^2 to 10^7; MST with 10^6 cells was 9.50 days.

Increased survival was observed in tumour-injected mice which were treated with either cyclophosphamide or ATuS, and was proportional to the total dose of drug or serum administered. The most effective ATuS regimen (0.25 ml./day) prolonged MST 53%, to 14.50 days. This was similar to the effect of 60 mg/kg of cyclophosphamide, or a 99.99% reduction in tumour inoculum, to 10^2 cells (Fig. 1).

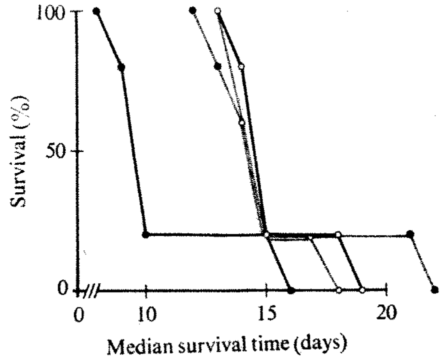

Fig. 1 Effect of rabbit antiserum, cyclophosphamide, or tumour dose reduction on median survival time.

	Tumour	Rx	MST	% prolonged
●——●	10^6	0	9.50	0
●---●	10^2	0	14.25	50
○——○	10^6	ATuS	14.50	53
○---○	10^6	Cy60	14.25	50

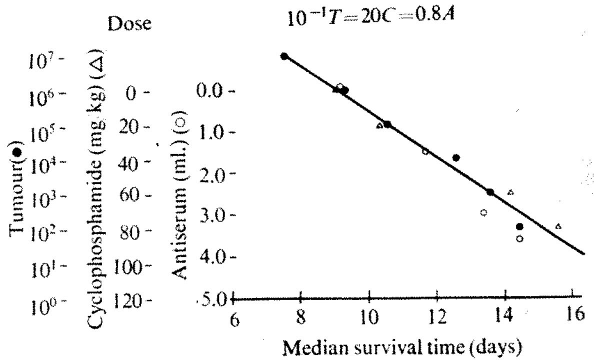

Fig. 2 Therapeutic equivalence of cyclophosphamide, rabbit antiserum and inoculum reduction (ATuS 5-69).

The dose related effects on survival are simultaneously displayed in Fig. 2, and are approximated as follows:

$$10^{-1}\ T=20\ C=0.83\ A$$

where T is the tumour dose (cells); C is the cyclophosphamide dose (mg/kg); A is the antiserum dose (total, ml.).

This experiment provides direct evidence for the hypothesis[17,18] that the effect of heterologous antiserum may compare favourably with the effect of chemotherapy in murine leukaemia. When produced and absorbed by methods similar to those used for ALS[19,20], heterologous antiserum seems to be of significant therapeutic benefit in passive immunotherapy of murine leukaemia.

Development of a Specific Anti-leukaemic Serum for the Treatment of Leukaemia in Clinics

LEUKAEMIC cells are antigenically indistinguishable from their normal counterparts and antibodies formed against them are therefore likely to exhibit cross-reactivity with normal cells. There is, however, a difference in the net surface charge[1]—the charge which regulates the ability of the antibodies to approach the target cells—which could be exploited to prepare antibodies specific to leukaemic cells. To this end, the net surface charge on the white blood cells of normal O group people was suitably altered by tagging the cells with chemicals such as 1-fluoro-2,4-dinitrobenzene (FDNB). These cells were then used as antigens for producing antibodies against human leukaemic cells in rabbits and horses. Here we give a brief account of the production of purified serum specific for leukaemic cells using immunized horse. A preliminary report on the production of specific anti-leukaemic serum from immunized rabbit has already been published[2].

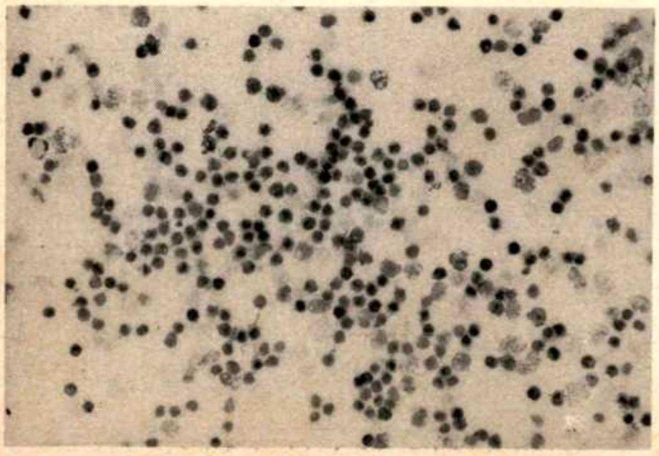

Fig. 1 Normal human WBCs treated with specific anti-leukaemic serum. No agglutination was seen.

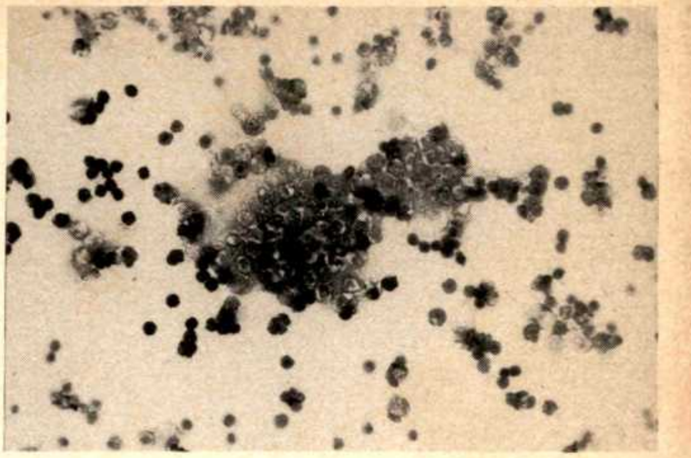

Fig. 2 Leukaemic cells treated with specific anti-leukaemic serum. Note the clumping and disintegration of the clumped up leukaemic cells.

Heparin, citrate or oxalate was added as anticoagulant to 300 ml. of blood from normal O group healthy people. Red blood cells were allowed to settle overnight with the help of dextran (5 ml. of 6% dextran to 100 ml. of blood). Supernatant and buffy coat were centrifuged to isolate the white blood cells. These were then alternately washed with normal saline and centrifuged at 600–800 r.p.m. at least five times to free the cells from plasma and anticoagulants. The few contaminating red blood cells were destroyed by a 30 s selective hypotonic shock[3,4] and the white blood cells were washed free of haemoglobin and stroma. This process was repeated until the white blood cells (WBCs) were completely uncontaminated. The viability of the WBCs was checked by the trypan blue dye-exclusion test of Ling[5]. They were then resuspended in normal sterile saline.

Saline suspension (1 ml.) containing 10^5 WBCs was mixed with 1 ml. of FDNB solution containing 10^9 molecules. The *p*H was adjusted to 7.2 and the mixture was shaken for 10 to 15 min at room temperature (22°–25° C). Untreated FDNB, if any, was removed from tagged cells by repeated washing and centrifuging (600–800 r.p.m.) with ten volumes of saline. FDNB tagged cells were resuspended in isotonic saline (10^7 cells/ml.). The tagged cells were again checked for viability by the dye-exclusion test.

Cell suspension (10 ml.) was injected subcutaneously to a horse each week for 22 weeks. The horse was then bled and the serum was prepared. The serum was heat inactivated and absorbed with pooled A, B and O human RBCs; the globulins were separated by ammonium sulphate and isoelectric precipitation[6]. The purified serum was tested for agglutination with leukaemic cells and normal WBCs (Figs. 1 and 2). Heparin was used as an anticoagulant[7] in the collection of blood samples. Non-specific aggregation of WBCs was prevented by minimizing the exposure of the WBCs to the anticoagulant (heparin) and by centrifugation at low speed (600–800 r.p.m.)[5] during the separation and washing of the cells. Titres were evaluated by the usual double dilution technique. Serial dilutions of the antisera were made with normal saline. Samples of 0.03 ml. containing 10^5 cells and 0.03 ml. of antisera at various dilutions were mixed in siliconized micro

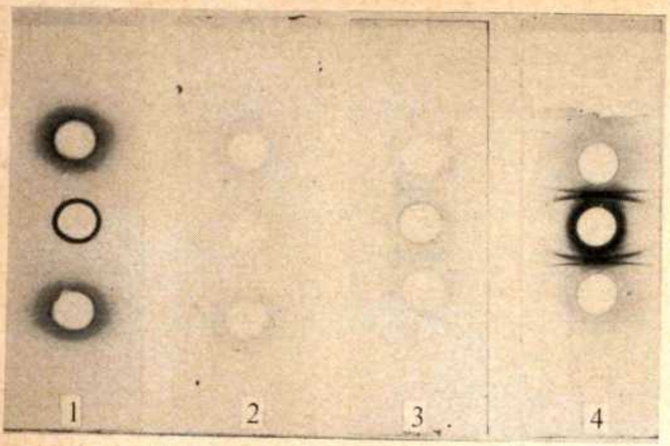

Fig. 3 Specificity of the anti-leukaemic serum demonstrated by the Ouchterlony gel diffusion method. Precipitation lines are obtained with leukaemic cells only. WBCs from normal subjects as well as plasma from normal or leukaemic persons did not reveal any cross-reactivity. Central well, anti-leukaemic serum. Top and bottom wells: 1, human plasma from normal persons; 2, human plasma from leukaemic patients; 3, membranous extracts of white blood cells from normal persons; 4, membranous extract of leukaemic cells. The extracts in wells 3 and 4 were from cells lysed by osmotic shock and the crude membranous material was extracted with mild alkaline solution (pH 7.4).

Table 1 Agglutination Titre with Purified Anti-leukaemic Serum against Leukaemic Cells separated from Leukaemic Patients

Patient No.	Blood group	Agglutination titre	Clinical diagnosis
Myeloid leukaemia cases:			
1	O	4,096	CML
2	A	8,192	CML
3	O	4,096	CML
4	B	4,096	CML
5	B	2,048	CML
6	O	2,048	CML
7	O	4,096	CML
8	AB	2,048	CML
9	A	2,048	CML
10	B	4,096	CML
11	O	4,096	AML
Lymphatic leukaemia cases:			
1	B	8,192	CLL
2	B	4,096	ALL
3	O	8,192	CLL
4	O	4,096	ALL
5	B	8,192	CLL

CML, Chronic myeloid leukaemia; AML, acute myeloid leukaemia; CLL, chronic lymphatic leukaemia; ALL, acute lymphatic leukaemia.

Table 2 Agglutination Titre with Purified Anti-leukaemic Serum against White Blood Cells from Normal People

No.	Blood group	Agglutination titre
1	B	0
2	O	0
3	A	0
4	B	0
5	O	4
6	A	0
7	B	0
8	O	0
9	B	0
10	B	0
11	O	4

13	B	2
14	AB	0
15	O	0

precipitin tubes and incubated at 37° C for 1 h. The tubes were centrifuged at 600–800 r.p.m. for 1 min and the degree of agglutination was determined. The maximum dilution of the serum which showed definite clumping (+1) was taken as the titre of the antisera. The specificity of the antiserum as well as the cross-reactivity, if any, with the plasma from normal human subjects and from leukaemic patients were studied by gel diffusion.

The agglutination titres are given in Table 1. The leukaemic cells were from a representative sample of sixteen leukaemic patients, eleven of whom had myeloid leukaemia, the other five having lymphatic leukaemia. Both types produced high titres compared with agglutination titres with normal WBCs (Table 2). The titres varied between 2,048 and 8,192 in both cases. Titres were negligible when normal WBCs were used.

The specificity of the anti-leukaemic serum was confirmed by clear-cut precipitin reactions with the leukaemic cells and by the lack of such precipitin reactions with normal WBCs (Fig. 3). Plasma proteins either from normal or leukaemic persons did not show any cross-reactivity. It is therefore clear that the anti-leukaemic serum is highly specific for leukaemic cells in general. A detailed report of purification, pharmacological studies and clinical trials will be published later.

Induction of Specific Autoimmune Response to Leukaemic Cells in Human Leukaemia Patient by Chemically Tagged Normal "O" Group White Blood Cells

WHITE blood cells from normal healthy O group people, when suitably tagged with chemicals such as 1-fluoro-2,4-dinitrobenzene (FDNB), can be used as antigens to stimulate the production of antibodies to human leukaemic cells in rabbits and horse[1,2]. We have shown that chemically tagged normal O group white blood cells can be used successfully to induce a specific autoimmune response to leukaemic cells in human leukaemic patients.

The serum of a 26 year old male patient with acute lymphatic leukaemia who had been treated with 'Endoxan' (100 mg/day), 6-mercaptopurine (150 mg/day) and prednisolone (60 mg/day), and who was on a maintenance dose of prednisolone (5 mg/day) when the experiment was initiated, was tested for the presence of iso-antibodies against leukaemic cells from other patients. He was then immunized for 7 weeks with chemically tagged O group WBCs as described below.

Blood was periodically withdrawn to check the iso-antibody levels. Because the patient had a history of short remission periods, 6-mercaptopurine (150 mg/day) was administered in addition to the prednisolone during the immunization period. The patient was discharged from the hospital after seven weeks of the immunization schedule and a blood sample was obtained a month later in order to check the antibody levels.

O group WBCs from normal individuals were tagged with 1-fluoro-2,4-dinitrobenzene (FDNB)[2]. A sample (1 ml.) containing 10^7 FDNB-tagged cells was injected subcutaneously into the patient each week. The site of injection was varied. The patient experienced no discomfort or ill effects as a result of injections and the schedule was continued for 7 weeks. Blood (10 ml.) was withdrawn before the immunization schedule began to find out whether there were any inherent iso-antibodies present. This was repeated each week to check the production of iso-antibodies against leukaemic cells. The iso-antibody titre was determined by measuring the degree of agglutination with leukaemic cells from other patients, and also by studying the agar-gel precipitin reaction with leukaemic cells. Both procedures have been described before[2].

The immunological responses of patients with acute lymphatic leukaemia are believed to be comparatively poor. In addition, the patient was being given prednisolone, an immunosuppressive drug[3], as a maintenance dose. Yet the iso-antibody titre increased to 256 after 4 weeks (Fig. 1). The agar-gel diffusion test also revealed a single, clear precipitin line (Fig. 2). During treatment, when the patient was dosed with 6-mercaptopurine (150 mg/day), another potent immunosuppressive drug[3], the iso-antibody titre did not increase but remained at 128. The iso-antibody titre remained at that level even after the immunization schedule had been discontinued. This investigation suggests that it is possible to elicit a specific autoimmune response to leukaemic cells by using non-malignant antigens. Further data on use of active immunization in patients and their clinical response will be published later.

Synthesis of Nitrosopiperidine from Nitrate and Piperidine in the Gastro-intestinal Tract of the Rat

MANY nitrosamines are carcinogenic to a wide range of animal species[1-4]. The synthesis of nitrosamines from nitrite and secondary amines has been demonstrated *in vitro* with animal and human gastric juice[5,6] and *in vivo* in animals[6]; nitrosamine synthesis was *p*H-dependent[6-9]. The synthesis of the non-carcinogenic diphenylnitrosamine has been reported in the human stomach after oral administration of nitrate and diphenylamine[7]. Nitrosamines can also be synthesized from nitrate and secondary amines *in vitro* at near neutral *p*H in the presence of enteric enteria[10]. We have demonstrated *in vivo* synthesis of nitrosopiperidine from nitrite and piperidine in the stomach and small intestine of the rat[11]. We report here *in vivo* synthesis of the carcinogenic nitrosopiperidine from nitrate and piperidine in the rat stomach and small intestine, and also with rat gastric contents *in vitro*.

Male Sprague–Dawley rats weighing 200–275 g were used. Methods used for *in vitro* studies with the gastric contents and for *in vivo* studies using the stomach or small intestine have been described before[11]. The ranges of *p*H values for stomach and small intestine were 3.4–4.3 and 6.3–6.8, respectively. For *in vivo* studies, solutions of sodium nitrate and piperidine were incubated for 30 min in the isolated intestine and/or in the stomach of the same rat or of different rats (Table 1). After incubation, intestinal and stomach contents were removed and extracted with dichloromethane as described before[11]; the solvent extract was dried overnight with sodium sulphate using a mechanical shaker. Nitrosopiperidine in extracts was quantitatively determined by gas–liquid chromatography[11]. The identity of nitrosopiperidine was confirmed by thin layer chromatography[12] and by additional use of another column of 3% QF-1 (Dow Corning fluoroalkyl silicone) on silanized gas chrom p. Using these techniques, the recovery from saline of a standard sample of pure nitrosopiperidine was 35%.

Table 1 Formation of Nitrosopiperidine from Sodium Nitrate and Piperidine Hydrochloride

	Reactant concentrations (mg)			Nitrosopiperidine yield† (μg)

4	1,250	25	13	8	2	32	1

* Each replicate is based on four rats.
† Estimated by gas–liquid chromatography.

Nitrosopiperidine was synthesized from nitrate and piperidine *in vivo* in the stomach and small intestine and from gastric juice *in vitro* (Table 1). Yields of nitrosopiperidine *in vivo* were generally somewhat higher in the stomach than in the small intestine, following incubation in the same or in different rats. Yields *in vitro* in the gastric juice were comparable with *in vivo* yields. These yields of nitrosopiperidine are underestimates in view of the relatively low recoveries of standard samples of nitrosopiperidine. Additionally, no effort was made to correct for nitrosopiperidine possibly absorbed during *in vivo* incubation.

The yields of nitrosopiperidine following *in vitro* and *in vivo* synthesis from nitrite and piperidine[11] were greater than for corresponding yields from comparable concentrations of nitrate and piperidine, as reported here. The synthesis of nitrosopiperidine even in small amounts, however, may have cumulative toxic effects, for nitrosopiperidine is a potent carcinogen[13]. Our results are in accord with human data on *in vivo* gastric synthesis of diphenylnitrosamine from nitrate and diphenylamine[7]; bacterial reduction of nitrate and nitrosamine synthesis in these studies was *p*H-dependent. The synthesis *in vivo* of the carcinogenic nitrosamine nitrosopiperidine from nitrate and piperidine is of practical interest in view of the common dietary occurrence of these precursors. Piperidine is a urinary constituent of normal human subjects, presumably formed by intestinal bacterial decarboxylation from dietary lysine[14]. Piperidine may also be ingested by man through some foods and spices; some bread flavouring agents contain piperidine[15]. Sodium nitrate and nitrite are used in the United States and elsewhere as preservatives and colour fixatives in cured meats and fish at permissible levels of 500 and 200 p.p.m. respectively[16]. Nitrite is also used alone at levels below 10 p.p.m. in smoked and cured tunafish. The use of nitrate or nitrite in certain types of cheese is permitted in some European countries. Nitrates are also widely distributed in many plants. Certain plants such as beets and spinach accumulate nitrates, especially when overfertilized[17] and in conditions of molybdenum deficiency[18–20]. Further, nitrate levels in drinking water, particularly in certain agricultural areas, may be high enough to induce acute methaemoglobinaemia in infants[21–25]. The transplacental transmission of nitrates and the development of methaemoglobinaemia in the foetuses of rats drinking water with high concentrations of nitrates has been recently demonstrated[26]. The implication of these findings to human cancer and the propriety of the continued use of nitrate and nitrite as food additives, and of drinking water with a high nitrate content, clearly merits critical consideration.

These studies were supported by grants from the US National Institutes of Health and National Air Pollution Control Administration.

Distribution and Concentration of Mercury in Autopsy Specimens of Human Brain

The dangers of mercury, a pollutant of natural bodies of water and a metal with a strong tendency to accumulate in the nervous tissues, have recently caused considerable concern. We have studied the distribution and concentration of mercury in the brain in order to determine the levels normally present.

Eight autopsy specimens were selected at random for the study. The subjects (Table 1) had lived, at least briefly, in an area where mercurial contamination of the regional inland waters and their fish has been demonstrated, but there was otherwise no known pathological exposure to the metal. The area includes Buffalo, New York, and the adjacent Great Lakes. Six brains were taken from the subjects 6–30 h after death; Nos. 1 and 2 were fixed in formalin before dissection. The tissues were analysed for mercury by neutron activation

Table 1 Content of Mercury in Various Regions of the Human Brain

Subject No.	1	2	3	4	5	6	7	8

Values are expressed as p.p.m. of wet weight tissue.

analysis (presented by S. K. K. P., C. C. Thomas, jun., and J. A. Sondel at meeting of Amer. Chem. Soc., 1971). After neutron irradiation the tissues were wet ashed in a nitric, sulphuric and perchloric acid mixture with mercury carrier in reflux conditions. A preliminary sulphide precipitation was followed by isolation of the mercury by electrodeposition. The radioactivities from ^{197}Hg and ^{197m}Hg were measured by gamma-ray spectrometry to determine the levels of the metal in the samples. This method readily allowed the quantitation of mercury in the range 0.01 to 2.0 μg/g of wet tissue with a sample size of 1–3 g. The accuracy was better than 15% at mercury levels of 0.01 p.p.m. and exceeded 5% at concentrations of 2 p.p.m.

The relatively small number of patients precluded the definition of absolute normal values but some valid observations can be made. As observed in Table 1, patient No. 6 is remarkable in that he had very large amounts of mercury in all regions of the brain except in the white matter. This patient had been considered a chronic alcoholic with chronic brain syndrome. He had acquired syphilis in 1929 but it could not be determined whether he had been treated with mercurial preparations.

Generally, the highest concentrations of mercury were found in the cerebellum. This led us to consider whether this structure normally contains relatively high levels of mercury or whether this element is preferentially accumulated at this site. The former assumption would appear tenable, at least to some degree, for in those subjects whose cerebellar values were not maximal, either all the regions of the brain including the cerebellum had very high levels (No. 6) or the cerebellar concentration tended to be relatively prominent (No. 7). Further support for this thesis can be inferred from the data of subject No. 4. The brain of this patient consistently contained the lowest or nearly the lowest concentrations of mercury in all areas studied in comparison with other subjects. The concentration in the cerebellum nevertheless exceeded the other areas in this brain in all instances but one by a factor of at least two. Conversely, the high incidence of clinically demonstrable cerebellar malfunction and gross cellular destruction in this region in patients with documented mercurial poisoning supports the concept of localized preferential accumulation[1,4]. The significance of the mercurial concentration in the foetal cerebellum (0.04 p.p.m.) could not be readily evaluated because of incomplete sampling due to post-mortem autolysis.

The pons is also of interest since in patients Nos. 2, 3, 4 and 5 the pontine concentration of mercury was exceeded only by that of the cerebellar cortex.

Except for the one brain that had a larger concentration of mercury (No. 6), the sampled areas of the formalin-fixed brains (Nos. 1 and 2) contained a greater amount than the other specimens. An analysis of the fixative was not performed.

The white matter of the hemispheres consistently had the lowest or near lowest levels in all individuals. This low profile suggests a correlation between anatomical structure and accumulation of the metal. The white matter is primarily composed of nerve fibres and is devoid of the cell bodies of nerve cells. Thus, this metal seems to be predisposed to localization in the perykarya of nerve cells rather than in dendritic or axonic processes. The ability of mercury to enter enzymatic reactions as well as its presence in microsomal and mitochondrial fractions of mercury-loaded nervous tissue[5] are consistent with this concept.

All regions of the brain examined revealed the presence of mercury. Since the observed levels are within the limits of accuracy of the method used, mercury may well be present as a normal constituent of neuronal tissue. Further studies are necessary to confirm this possibility.

We thank Dr Walter Olszewski, Buffalo General Hospital, for supplying the human brains.

Accelerated Elimination of Methyl Mercury from Animals

WE wish to suggest one principle that may be valuable in the treatment of methyl mercury poisoning—the notion that continuous oral administration of indigestible unabsorbable SH-compounds such as reduced hair powder may accelerate the elimination of methyl mercury from mice.

Organic mercury injected into animals is known to be[1,2] fairly well excreted into the bile for a considerable time and we have confirmed this result and have studied the chemical nature of the mercury excreted into bile after three rats (weighing about 200 g) were intramuscularly injected with 2 mg of methyl mercuric chloride each day for 5 days. The rats were killed 48 h after the last injection and the contents of the small intestine from three were washed out with 0.95 M phosphate buffer (*p*H 7.0) and pooled. The total mercury found in this material was 106.6 µg and about 85% of it was found in the high speed supernatant. The supernatant was used for the following studies. When a portion of it was treated with 1 M HCl for 1 day, extracted with benzene, and run on a gas chromatograph column containing 10% 1,4-butanediol succinate on 'Chromosorb W' and fitted with an electron capture detector, 83% of the mercury was found to be in the form of methyl mercury. It is not clear whether the rest of the mercury is organic or not. When the supernatant was directly extracted with benzene, 23% of the mercury was present as free methyl mercuric chloride. And when the supernatant was dialysed against forty volumes of 0.05 M phosphate buffer (*p*H 7.0) for 24 h, 80% of the mercury was found to be in the form of dialysable, low molecular derivatives. When 1 g of human hair powder treated with thioglycollate as described later was added to the supernatant, 82% of the mercury was bound to the hair powder and precipitated during 30 min incubation at 37° C. After repeating the experiment and obtaining a very similar result, our conclusion was that most of the mercury excreted in the bile was methyl mercury in the form of its chloride or low molecular weight compounds.

We thought that trapping these forms of mercury and protecting them from reabsorption from the intestine would decrease the accumulation of mercury in the animals. To test this idea we prepared human hair powder reduced with thioglycollate, a substance that has a good methyl mercury binding capacity because of the cysteine SH group and because it is resistant to trypsin digestion. About 20 g of clean human hair was cut into very small pieces with scissors and ground with a strong conical homogenizer in 400 ml. of dilute ammonia (*p*H 11) containing 9.3 g of thioglycollic acid. After adding another 5 g of thioglycollic acid the mixture was allowed to stand at room temperature for 2 h under nitrogen. The precipitates were collected by centrifugation, washed once with plenty of water and three times with acetone and with ether. The material was dried and stored in an evacuated desiccator. One gramme of this material could bind 60–70 mg of methyl mercuric chloride. It could also recover 80% of 100 µg of methyl mercuric chloride injected into mice. In this experiment, a whole mouse (20 g) was ashed with 20 ml. of concentrated HNO_3 and 20 ml. concentrated H_2SO_4 for 5 h and then reheated for 30 min before addition of 5 g of potassium permanganate. The mercury content of the ash and the recovery were measured by the dithizone method[3,4]. In a feeding experiment twenty-eight female mice (16–17 g) of the DD strain were poisoned by a single intramuscular injection of 200 µg of methyl mercuric chloride in saline solution and divided into two groups; one was fed on ordinary food (CREA II) and the other was fed the same diet plus 3.3% hair powder for 10 days. In another experiment thirty-four mice were poisoned with 400 µg of methyl mercuric chloride and the feeding was continued for 20 days. They were then killed. The results of mercury analysis of each animal are shown in Figs. 1 and 2.

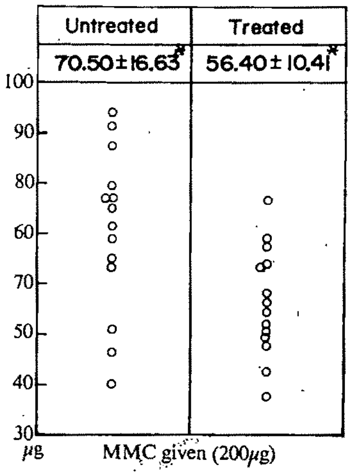

Fig. 1 Total mercury after 10 days. *Mean ± s.d. The difference was significant ($P < 0.005$).

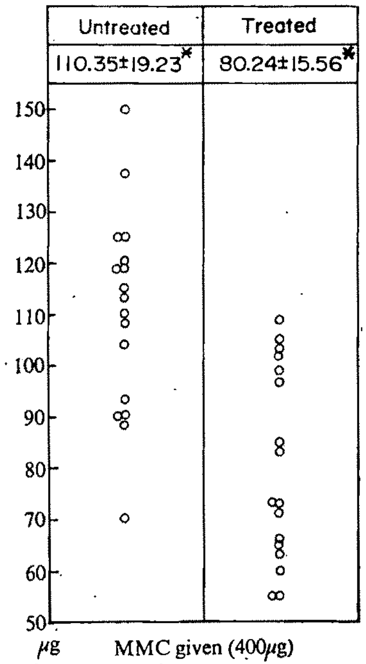

Fig. 2 Total mercury after 20 days. * Mean ± s.d. The difference was significant ($P < 0.005$).

The reduced human hair powder reduced the level of the residual methyl mercury in the mice poisoned with methyl mercuric chloride, indicating that methyl mercury excreted into intestine is eliminated by this procedure in the faeces. The results also suggest that reabsorption of methyl mercury excreted into bile is one of the reasons for the prolonged biological half life of methyl mercury in the animal and that any material which has methyl mercury binding capacity and is resistant to digestion and absorption from the intestine could be useful for eliminating methyl mercury from animals. Third, synthetic resins with SH groups may be effective for the same purpose. The procedure may be used in cases of accidental ingestion of organic mercury or it may be used prophylactically when food is consumed that is contaminated with methyl mercury.

We thank Dr Motoo Fujiki for assistance with gas chromatography.

Two-stage Recovery of a Response in *Sepia*

A RESPONSE that has waned as a result of continuous stimulation without reinforcement may reappear when the stimulus is presented on another occasion: habituation, as defined by Thorpe[1], is "relatively permanent" but not complete. The extent of recovery of the response will clearly be a function of the length of time between presentations, but several workers, notably Hinde[2,3], have shown that the relation between recovery and rest interval is not a simple one. Recovery seems to occur in at least two stages, possibly reflecting the existence of separate underlying physical processes. Some recent experiments with the cuttlefish, described here, have revealed a two-stage recovery with much sharper separation than has been found previously.

Cuttlefish (*Sepia officinalis* L.) feed on prawns, which they capture by a rapid strike with the paired tentacles[4]. The strike is elicited entirely by visual cues so that a prawn presented behind glass is attacked in the usual way. Since the strike fails to seize the prawn, the cuttlefish attacks repeatedly but the rate of striking soon begins to diminish and a typical decremental response curve is obtained. We are here concerned only with the recovery of the response after it has waned: specifically, does the number of stikes in a second presentation period depend on the interval since the first presentation period?

A 'Perspex' cylinder containing seawater and two prawns was placed in a tank about 50 cm from a naive cuttlefish and was then left there for 20 min. During the first 5 min of this period the animal was observed and the number of strikes (*a*) it made was recorded. After a further 15 min, during which the animal was not observed, the tube was removed for an interval and was then replaced for a further 5 min. The number of strikes (*b*) in this second period was recorded and the ratio $\left(\frac{b}{a}\times 100\right)$ was calculated to give a measure of the percentage recovery of the response for that animal. Animals were tested after eleven different intervals varying from a few minutes to a day. At least twelve animals were tested after each interval; twenty were tested after the intervals 22 min, 30 min, 45 min and 60 min. Each cuttlefish was tested once and then discarded.

As would be expected the response (Fig. 1), which had waned almost completely during the 20 min initial presentation period, showed no recovery when the prawn was offered a few minutes afterwards. More surprising is that even 24 h later the response had only recovered to about 14% of its former value. These animals therefore showed considerable retention. They rarely attacked an animal that is their natural prey, though they attacked crabs presented at the end of the second presentation period: the waning of the response was evidently stimulus-specific and not simply the result of sensory adaptation. Moreover, because crabs were often caught with the tentacles (instead of with the arms alone[5]), it is unlikely that motor fatigue is an important factor in the waning of the response.

It is interesting that the recovery curve is not smooth: the response began to recover and then declined, until at 60 min it had almost disappeared. It then recovered again and by 90 min the response had apparently reached asymptote. That the "dip" in the curve between intervals of 22 min and 90 min is not the result of random fluctuation can be shown by χ^2 analysis of the frequencies of attacks during the first and second presentation, for all these rest intervals. In a 2×5 contingency table $\chi^2=34.89$ (d.f.$=4$, $P<0.001$). Furthermore, there is a highly significant difference not only between performance at 60 m and 90 m ($\chi^2=33.28$) but also between 60 m and 45 m ($\chi^2=13.78$); for both $P<0.001$ (d.f.$=1$). The experiment thus produces the apparently anomalous result that cuttlefish retain more about an event after 1 h than after 20 min.

How can this curve be explained? If it were classical "habituation" Hinde would claim that it results from the interaction of incremental and decremental processes with differing time courses, as, for example, in the recovery of the chaffinch mobbing response[3,6]. But on present evidence the possibility cannot be excluded that the behaviour is being influenced by negative reinforcement, by pain input from receptors in the tentacles. Several hard strikes of the tentacles on the 'Perspex' may be ample for learning in such fast-learning animals[7]. This experiment, then, may provide an example of a conventional "learning" situation. In such a situation Sanders and Barlow[8] have collected data for *Octopus* which show a tripartite retention curve, and their interpretation of this is that there are three memory systems: short, intermediate and long term. It is interesting that the transition from what they call "short-term" to "intermediate" memory occurs at a comparable time to the transition between the two stages of recovery shown here in *Sepia*, which could also be due to the operation of memories of differing time-course.

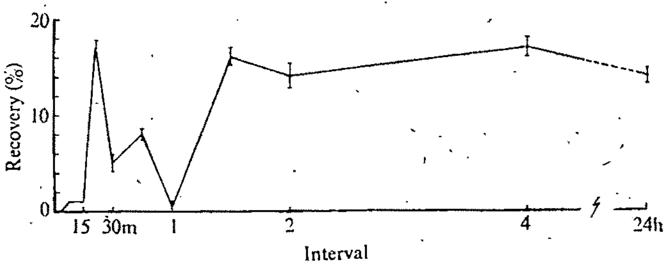

Fig. 1 Percentage recovery as a function of rest interval. Each point is the mean of at least twelve animals: bars indicate s.e.m. Means and s.e. were calculated after arcsin transformation of percentage scores.

This work was supported by the Science Research Council. I thank the staff of the Stazione Zoologica, Naples, for use of facilities there, and J. J. Barlow and G. D. Sanders for much helpful discussion.

Variations in Retention Performance during Long Term Memory Formation

RETENTION performance as a function of time generally follows a typical monotonically decreasing curve[1-3], but there are a few reports showing an improvement with time[4-9]. Monotonic retention curves have been obtained with octopuses for short-term memory (STM)[10] and for long term memory (LTM)[11]. Here we present a preliminary report of one of a series of experiments using a rapid training procedure which enables us to study changes in retention performance over a period presumed to include the time courses of both STM and LTM.

Experimentally naive *Octopus vulgaris* (150–400 g) which had been in the laboratory for at least 5 days were used when they were attacking and eating crabs readily. These octopuses were trained not to attack a crab (*Carcinus*) in conditions similar to those in which Young[12] has shown that learning is stimulus specific. Training began by placing the crab, tied to a transparent rod, in the home tank at about 50 cm from the octopus. Just before the octopus completed its attack the crab was removed, the octopus was given a 4 V a.c. shock and the crab was immediately replaced. (An attack was judged to have occurred when it was necessary to remove the crab in

Pur Che istry Library

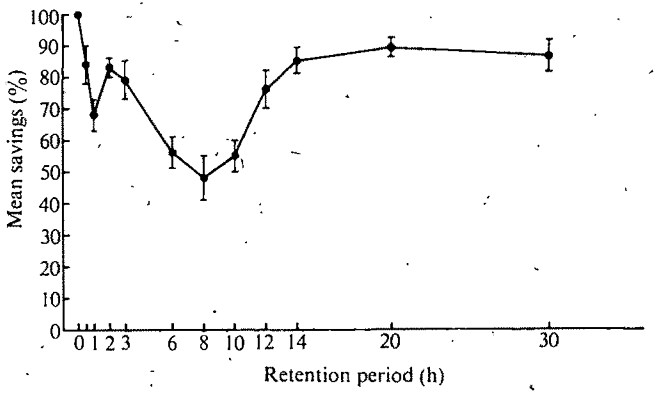

Fig. 1 Retention curve based on the mean percentage savings of octopuses trained and retrained using a 4 V shock to a criterion of no attack on a crab for a period of 1 min. Each point represents the mean scores of six or seven animals. The vertical bars mark one standard error above and below the mean.

order to prevent the octopus from touching it with its arms.) This sequence was repeated until a criterion time of 1 min passed during which there was no attack on the crab. The number of attacks and their latencies were recorded. Different groups of octopuses were retrained by the same procedure after retention intervals of 0.5–30 h. The groups were trained at different times throughout the day so that all retraining occurred during the same period (15.00–19.00 h). The differences between the attacks on training and retraining, expressed as a percentage of the training attacks (% savings), were used as a measure of retention performance. No octopus was retrained more than once.

The mean percentage savings (Fig. 1) decrease rapidly to 68% at 1 h but greater savings are made at 2 h (83%). From 2 h the savings fall steadily to 48% at 8 h only to increase again until at 20 h the octopuses show greater savings on retraining than at any previous time. Retention performance is still good at 30 h. The savings at 1 h are significantly lower than those at 0.5 h ($t=2.00$, $P<0.1$) and at 2 h ($t=2.50$, $P<0.05$). The savings at 8 h are significantly lower than those at 2 h ($t=4.52$, $P<0.01$) and at 14 h ($t=4.59$, $P<0.001$). The octopuses retrained at 1 h made nearly twice as many attacks as those retrained at 2 h while the difference in retraining attacks between 8 and 14 h was three-fold (Table 1). It seems, therefore, that in these conditions retention performance is not monotonically related to the length of the retention interval.

Table 1 Number of Attacks made at Various Intervals after Training

	Retention period (L)										
	0.5	1	2	3	6	8	10	12	14	20	30
No. per group	6	6	6	7	6	6	7	6	6	7	6
No. of training attacks: mean	13	15	15	16	15	15	18	18	16	16	14
s.d.	3.7	4.8	4.4	5.4	2.6	4.4	3.4	4.6	5.6	5.4	3.4
No. of retraining attacks: mean	1.8	4.7	2.7	3.1	6.3	7.7	8.0	4.5	2.3	2.0	2.0
s.d.	1.1	1.7	1.5	2.1	1.2	2.9	2.1	2.7	1.5	1.7	1.9

Several variables may have affected the tendency to attack. All octopuses were last fed with crabs during the afternoon of the day before they were trained. The time between feeding and retraining was therefore about 24 h for all except the 20 and 30 h groups. Thus the principal variations in the numbers of retraining attacks were all obtained at approximately the same hunger level. To carry out retraining during the same part of the day and at the same hunger level, training was given at different times of day. The numbers of training attacks may, therefore, have been influenced both by the hunger level and by possible variations in the daily activity pattern of the octopuses. The mean training attacks do show some variation (Table 1) but they are not correlated with the mean numbers of retraining attacks ($r=+0.42$, not significant at the 10% level). The differences in training performance would not account for the shape of the retention curve. Changes in activity during the day would not have influenced the retraining attacks as all retraining occurred during the same part of the day. The variation in sea water temperature (16–19° C) was probably not sufficient to have affected the results. We conclude that the variations in the retraining attacks are dependent on the length of the retention interval.

Although there may be other explanations of the shape of this curve we think it most likely that it reflects the state of the available memory. The results would then indicate that the memory for an event is maintained by three processes with different rise and fall times. These may be identified as STM, an intermediate memory (IM) and LTM. According to this hypothesis STM appears during training and declines rapidly, IM appears at about 2 h and declines less rapidly than STN, while LTM appears after approximately 12 h and declines slowly. The STM and IM control behaviour until LTM is available. A similar curvilinear function has been obtained by training *Octopus* with a 10 V and a 3 min criterion. Other combinations of these parameters tended to produce monocurves with different overall levels of retention performance. This suggests that the present results can be observed only within a limited set of training conditions. A detailed report of these experiments is in preparation.

Previous investigators have found dips in retention curves at 1 h using rats[4,5], at 30 min using cuttlefish[9] and at 2 min (ref. 6) and 30 min (ref. 8) using mice. None of these experiments included systematic tests between 2 and 24 h and so there are, to our knowledge, no reports of the second dip which we find with *Octopus* at 8 h. Evidence for multiple memory storage has depended to a large extent on demonstrations of the selective blocking of memory with electroshock, anaesthetics or antibiotics. On the basis of this evidence Booth[13] has estimated the time courses of successive physical mechanisms for holding retrievable information during memory consolidation. His expected rise and fall times for the three mechanisms are comparable with those obtained in the present experiment. In view of these observations it seems possible that a system of three memory processes may be universal.

This work was financed by a grant from the Science Research Council of Great Britian and, in part, by a fellowship from the Royal Society (G. D. S.). We thank Dr J. B. Messenger for showing us his results before publication.

BOOK REVIEWS

Communities of Sciences

Politics and the Community of Science. By Joseph Haberer. Pp. vi + 337. (Van Nostrand Reinhold: New York and London, February 1971.) £4.50.

Few would disagree with the statement of Dr Haberer that there is a crying need to throw "some light on the political nature of the community of science" and "the political behaviour of its members". Unfortunately, his book, which has been well received in the United States, strikes me as singularly unilluminating.

Professor Haberer is a political scientist who wishes to use history for the purpose of illustrating arguments about how scientists ought to act during social and professional crises. For the author, understanding the past on its own terms is clearly a secondary activity: "political analysis", he asserts on page 218, "does not require exhaustive historical reconstruction". We then must wonder why he devotes several hundred pages to case studies dating back to the seventeenth century. If Haberer is at all serious about the types of evidence he uses, his work must be judged in terms of not only the concision of his concepts but the accuracy of his examples as well.

The author's basic thesis is that scientific communities, when faced with the possibility of severe external sanctions, tend to practise "the politics of prudential acquiescence". According to him, such a tendency derives ultimately from two components of the scientific role, namely lust for power and intellectual arrogance. These norms, in turn, generate a community characterized both by a strong methodological ethic (truth-seeking) and by a weak institutional one. It is the latter quality, in Haberer's view, which generates political "sell-outs" on the part of scientists. Needless to say, this is hardly an attractive picture of scientific life, and we therefore turn with some interest to the data which ostensibly verify it.

From the last three and a half centuries of the history of modern science, the author has selected three incidents to sustain his narrative. The first involves the biographies of Bacon and Descartes (which also serve as his ideal-type projections of the 'Baconian' and 'Cartesian' scientist). Next comes the experience of leading German scientists during the period of Nazi rule. Finally, we are treated yet again to an exposition of the Oppenheimer affair.

Before analysing the specific events as Haberer discusses them, I think it best to detail a few sins of omission on his part. Surely a treatise on the political behaviour of all Western scientific communities from 1600 to the present which neglects the period 1650–1933, the accumulated experiences of British, French, Italian and Russian researchers, and the activities of all scientists save physicists cannot pretend to be representative, much less exhaustive. The failure to discuss at all the disparate ways in which science became a professional activity in different national settings during the nineteenth century is particularly astonishing, because this process lies at the heart of current battles over the social responsibility of scientists. (Equally astounding to British scientists of interwar vintage will be the author's assertion that "social responsibility" is purely a post-war concern.) I could only wish that Professor Haberer had bothered to explore, however haphazardly, post-Kuhnian developments in the history and sociology of science.

What about his examples? I just cannot see how the relevant scientific communities violated their professional values by refusing to support such court politicians as Bacon and Oppenheimer. Of course this statement sounds ludicrous when applied to Bacon, not only because he was not a scientist but also because there was no scientific community available to protest his downfall. As for the German scientists under Hitler, Haberer's lack of historical perspective leads him to condemn them on the grounds that they lacked the "civic courage" shown by such institutions as the church and the military. Leaving aside our feelings about the scientific community's relationship to Naziism, we should ask whether the author has made the right comparisons. I do not believe he has. The real question is: did the responses of German scientists differ significantly from those of social groups existing in similar institutional contexts, namely other German academics? To the best of my knowledge the answer is negative, which means that we should, in the first instance, look at the operation of the German university system rather than the universal norms of scientific life. Strangely enough, Fritz Ringer's account of *The Decline of the German Mandarin*, without directly discussing natural scientists, is a far more reliable guide to the actions of the scientific community than Haberer's book.

The author's handling of the Nazi episode really lays bare the poverty and amorphousness of his conceptual structure. What is the community of science? The attempt of Haberer to subsume all scientists and engineers working in academic, governmental, industrial and independent laboratories into a single, transcendent structure flies in the face of atomized, contemporary realities. How representative of the entire "community" are the actions and statements of leading scientists? Here the author assumes a fairly close correlation between leaders and led without ever supporting this notion either theoretically or empirically. What are the values of science which political action might threaten? Here Professor Haberer is at least of three minds. For most of the book, he talks about truth-seeking and independence of judgment. In the final chapter, however, we are told about the advancement of national or humanitarian goals. But he is also led to wonder "whether the community of science has any ultimate or intrinsic values at all—or if any are expressed in the institutional life of the enterprise". How then do we escape from such intellectual and moral bewilderment? At this point, the author comes dangerously close to adopting the "disestablishment of science" recently advocated by Bronowski—a utopian counsel of despair which, to my mind, is as politically irresponsible as it is impracticable.

Given the fact that *Politics and the Community of Science* is a pioneering effort, I realize that I may have been too harsh in my criticism. The reason for this is quite simple. I share the author's conviction—and not a few of his prejudices—that the political role of science in modern society may be the next generation's most critical problem. Apart from a serious and more general commitment to politics as such, we desperately need more hard thinking and judicious inquiry into this subject. I would not like to see such an effort guided by the methods of Professor Haberer.

P. G. Werskey

Cells in Charge

Cell Differentiation. Edited by A. Ole Schjeide and Jean de Vellis. Pp. xvi + 606. (Van Nostrand Reinhold: New York and London, February 1971.) £10.

Any biologist who has the stamina to read this book from cover to cover will emerge tired, but well informed about most of the approaches which are used to study differentiation at the cellular level. But the book describes the state of play, as it were, early in 1968; although the volume is published only this year, I could find no references to work reported in the literature after 1968, comparatively few references to work reported in that year, and citations to "recent reviews" proved to refer to articles published in 1967 or even 1966. But it is a mark that the book is well written and put together that comparatively little of what it says would now be regarded as misleading; it is merely a shame that the further experiments performed in the past year or so, which in some instances confirm suggestions made by the authors, are not presented to buttress these conclusions.

The first section of the book, entitled "General Concepts", comprises three chapters, the first of which, written by the two editors, should be compulsory reading for all cell biologists; this brief discussion is notable for the sense of perspective which it conveys of cell biology in general and of the succeeding chapters of this book in particular. But the two chapters which follow are perhaps a little too theoretical to fit well with the other, experimentally orientated chapters, and are unlikely to appeal to the graduate student level audience at which the book seems to be aimed.

The second and fourth sections are probably the most valuable. The second section, molecular biology, starts with a chapter which is very largely a review of the classical molecular biology of bacteria; as such this is not particularly valuable, for there are many other competent treatments of this subject. Although the editors no doubt felt that it would be best for this book to be complete in itself, I doubt the usefulness of yet another review of the evidence that DNA is the genetic material, to cite one example. A volume written at this level would do better to take for granted the classic studies of nucleic acid and protein synthesis and to turn directly to its topic. But, that said, the remainder of this section, which discusses the transcription of RNA, the cell cycle, nucleocytoplasmic interactions and membrane functions, is well written, reasonably thorough, and is bound to be useful for reference.

The succeeding section, on biochemistry and metabolism, which is concerned with topics such as the ageing of cells and changes in enzyme and other protein activities during differentiation, is perhaps too didactic to be more than a sidestream in cell differentiation.

The final section, which makes up half of the book, is concerned with particular systems which are being used to study differentiation. The first two chapters concern the differentiation of the cell as such, that is to say, the synthesis of structures such as polysomes and the endoplasmic reticulum. The chapters which then discuss the details of several individual systems are all useful as reference works describing the situation as it was early in 1968.

A notable omission from the book, which is perhaps not surprising in view of its age, is a discussion of cell hybridization and the uses to which this versatile technique may be put. If a second edition is prepared, the editors would do well to perform some judicious pruning, especially on the two more speculative chapters of the first section and of the review of molecular biology. A book of this nature is at its most useful when recently written, so it is to be hoped that such delays in production will not be repeated. And it is fair to add that a book as large and complex as is this one is only as useful as its index, which is, alas, so perfunctory as to be useless.

Benjamin Lewin

Introducing Microbes

Micro-organisms: Function, Form and Environment. Edited by Lilian E. Hawker and Alan H. Linton. Pp. xxii + 727. (Arnold: London, January 1971.) £6.

In an effort to provide an up to date undergraduate text in microbiology, Professor Lilian Hawker and Dr Alan Linton have enlisted the aid of twenty of their colleagues, each contributing one or more specialist chapters or sections. The aim has been to survey the whole field of microbiology so as to make it readily understandable by first year university students. Only a relatively small part of the book is devoted to strictly biochemical and genetical topics, an imbalance which has been made deliberately by the editors, who feel that this material is covered extensively in the existing textbooks. Discussions of growth and viability are followed by the two largest sections of the book, which deal with microbial structure, life cycles and classification and with microbial ecology. The final few chapters are devoted to selected aspects of economic microbiology.

The greatest difficulties confronting editors of a text produced in this way are those of achieving conformity of style, and balance and integrity of material. It is clear from the cross-referencing that the editors have been at pains to try to interrelate the contributions of the various authors but, nevertheless, a disappointment of the book for me was that the integration was not more fully realized. The treatment of growth physiology is the best to be found in any text at this level and, in particular, continuous cultivation is given much more than the usual nominal treatment. It is unfortunate therefore that reference to the application of steady state systems was not made by other contributors, who missed an ideal opportunity of emphasizing the dynamic nature of the chemistry, structure and functioning of microorganisms. In this context a rearrangement of chapters might have helped. For example, discussion of microbial nutrition and the effects of environmental parameters on growth could have been more effective after the reader had been introduced to chemostasis.

All the major groups of the Protista are covered comprehensively and the discussion has been based firmly on classical taxonomies. The latter approach does not make very compulsive reading but, at the same time, the student will be able to discover readily the breadth of his subject and find his way around the diverse groups of microorganisms. This section concludes with a useful account of numerical taxonomy but surely the reader deserves an assessment of the success of this rediscovered system of classifying, how it works out in practice and how widely it has been applied, without having to resort to the specialist primary literature. My only quibble with the otherwise interesting discussion of economic microbiology is that it tends to be too descriptive. The reader will find little or nothing on process design, applied genetics, new fermentation methods or cost analysis, all of which are of crucial importance to the industrial microbiologist.

The few reservations which I have about this book are offset by its general excellence, and certainly it will figure on my list of recommended first year texts. Microbiology is presented in the widest possible sense and the contributions from specialist authors have provided some fascinating and stimulating reading. The illustrations have been chosen with great care and are of the highest standard; they add much to the reader's comprehension and pleasure. Indeed, the whole production has been meticulous, and remarkably few printing or other errors have impinged on my eye. Specific bibliographies have, on the whole, been well selected and, most important in my view, the book is supplied with a good index. In conclusion this is a most welcome addition to teaching texts in microbiology and even if the price is high it is, alas, not now unusual for books of this kind.

Alan T. Bull

Bug Killers

Naturally Occurring Insecticides. By Martin Jacobson and D. G. Crosby. Pp. xii + 585. (Dekker: New York, January 1971.) $33.75.

The increasing apprehension over the use and persistence of synthetic insecticides on the one hand, and the build-up of insect resistance to many of these compounds on the other, has led scientists to search for other methods of chemical control of harmful insects. Fortunately there were already leads to be followed in existing biological control, and this book sets out to review the chemistry, biochemistry, toxicology and biology of the various compounds involved. The book is presented in three sections, depending on the source of the insecticides: botanical, insect-derived, and bacterial and fungal. Each chapter is written by a world authority on the subject although naturally there is considerable variation in the thoroughness of the treatment, and each has its own collection of references to the original literature.

The first section comprises chapters on the pyrethroids, rotenone and the rotenoids, nicotine and other tobacco alkaloids, the unsaturated isobutylamides and finally minor insecticides of plant origin. Each of these chapters contains detailed chemical treatment of the compounds involved as well as descriptions of application and effectiveness of treatment. The second section deals with arthropod venoms, and secretions and cantharidin, the juvenile hormones, and the ecdysones. Unfortunately the chapter on juvenile hormones, unlike most of the others, contains little chemical information on determination of structure and nothing on the numerous synthetic approaches to this important compound. In the final section the use of *Bacillus thuringiensis* as a microbial insecticide and a description of the chemistry and application of the destruxins and pericidins is given. The book is the first collection of such material and will be an important reference volume for the many scientists working in this large area. Unfortunately there are very few references to work published within the past two years which, therefore, excludes reference to much important work in this rapidly expanding field.

A. W. Johnson

High Speed Introduction

An Introduction to Ultracentrifugation. By T. J. Bowen and A. J. Rowe. Pp. xviii + 171. (Wiley-Interscience: London and New York, December 1970.) £2.50.

The ultracentrifuge is now so fundamental to the study of proteins and nucleic acids that an early introduction to the machine must form an essential part of the training of the research worker in these fields. And while there are several excellent reviews and monographs devoted to its use, an elementary but comprehensive text has so far been lacking. This book is intended to fill this gap; as the preface emphasizes, the treatment is purposely elementary, and the mathematical content approaches the minimal. Judgment on the book must accordingly be made within this frame of reference.

In the introductory chapter, the elementary theory of sedimentation velocity and its relation to molecular weight are outlined, and some of the early and now classical results are surveyed. The characteristics of the more important modern analytical instruments are then summarized; one wishes, perhaps, that the authors had been less guarded in their reference to the costs of maintenance and spare parts. Optical systems are described clearly: the diagrams illustrating the relation between the type of cell and the patterns it provides will be particularly useful to the beginner.

A chapter on the determination of sedimentation and diffusion coefficients, and a discussion of their significance, is followed by one devoted to the Lamm equation. Even allowing for the author's purpose, the treatment seems over-simplified: phrases such as "the velocity of the solute molecules" are to be found, and equilibrium is referred to as a "steady state". The treatment of diffusion is in terms of opposing osmotic and diffusion pressures (surely hypothetical) and the force-friction concept; to me, the phenomenological treatment of Gosting and others seems preferable, in its adherence to strictly operational concepts. Nevertheless, the essential significance of the transport coefficients is adequately described, and their relationship to experimental measurements established. The treatment of the continuity equation is detailed, but the attempt to avoid partial differentials leads to a rather cumbersome form for the important equations: once again, the explicit formulation of a flow would lead to a simpler result.

Sedimentation equilibrium is now firmly established as a principle of major importance in ultracentrifuge work, and the value of a book in this field must depend significantly on the clarity with which the essential concepts are described. It is sufficient of a comment that the equations of equilibrium are described here only in the context of zero flow: it is regrettable that the instructive comparison between equilibrium and the Archibald principle is thereby lost.

In the chapter on the determination of molecular weights, the most important of the many methods now in use are described. Due prominence is given to the high speed method of Yphantis but there is no guidance on the fundamental question of speed selection, nor is the simple expression stated for the time taken to attain equilibrium.

The chapter on the determination of molecular conformation provides a useful summary of procedures based on hydrodynamic models and this leads naturally to a discussion of the intrinsic viscosity and how it is determined. One might question the necessity for some of the detail in this section; Tanford's explicit equations relating the sedimentation coefficient and the intrinsic viscosity to the molecular weight of proteins as random coils could usefully have been included.

In the analysis of mixtures by sedimentation velocity, two complications are well recognized, if not always allowed for: these are the Johnston–Ogston effect and the more specific molecular associations associated with the name of Gilbert. Both these topics are discussed, and the essential precautions set out.

Dr Bowen's final chapter is concerned with preparative ultracentrifugation. It describes how preparative runs can be planned intelligently, and collects together much material that is widely scattered in the literature and in makers' manuals. The relative advantages of different types of rotor are assessed, and many quantitative comparisons are made: the section should be of particular value to people concerned with zonal separations.

The last two chapters, by Dr Rowe, are concerned with applications and some commonly encountered problems. Appropriately, emphasis is given to the problem of assessing the degree of homogeneity of substances examined in the analytical ultracentrifuge. As the author states, much of the evidence concerning homogeneity presented in the literature is not wholly convincing. The standard methods based on velocity measurements are described; in those based on sedimentation equilibrium, reliance is placed heavily on the very recent methods evolved by the author himself. It would have been helpful to have included the informative examples of Fujita and Williams. Some good examples of typical conformational changes in proteins and nucleic acids are quoted.

In the section on problems, some

typical questions are answered, and ways of overcoming difficulties suggested. There is much sense in this, although the occasionally flippant style may not be to every reader's taste. Some numerical problems are also included, with answers.

Although most of the errors are relatively trivial, some could mislead the inexperienced worker. Thus, on page 46, the suggested method for determining diffusion coefficients will not give a straight line plot; the defining equation for $\bar{v}$ (page 56) has an unnecessary subscript which obscures the significance of the differential; the initial concentration in the example of the Yphantis method (page 68) must be wrong by at least an order of magnitude. Most seriously, in the section on the Archibald method, the concentration at the meniscus is erroneously identified (equation 6.23) with the difference between the initial and plateau-region concentrations. Although this mistake is repeated in the example, the meniscus concentration is correct. Equations 6.26 and 6.27 are incorrect. In equation 7.20 the critical subscript to the partial differential is undefined. On pages 152 and 153, the symbol "Γ" appears where "ρ" is intended; once again, the critical subscript is omitted. Equation 10.12 is incorrect: the quantity ϕ' defined by Casassa and Eisenberg should replace $(\partial l/\partial c)$.

In spite of these errors and omissions, and some deficiencies in editing, I feel that this book's purpose has been achieved. The student who has read it will be in a position both to perform simple experiments and to understand the more rigorous approach of the primary sources, to which he will be led by generally excellent documentation. At its modest price, the book is good value.

J. M. CREETH

Electron Optics

Electron Optics. By O. Klemperer. Third edition in collaboration with M. E. Barnett. (Cambridge Monographs on Physics.) Pp. ix+506. (Cambridge University: London, January 1971.) £9.

THIS third edition is probably the best and most comprehensive introduction to electron optics currently available in English. It reflects the considerable developments that have taken place since the previous edition was written in 1953. In spite of the addition of a considerable amount of new work, the size of the book has increased by only seven per cent, the result of some vigorous pruning and rearrangement of material.

Descriptions of miscellaneous standard electron optical devices have been replaced by topics of a more fundamental character. The result is a work that reveals, with much greater clarity than before, the essentials of the subject. The authors have taken special pains to anticipate and alleviate the difficulties often experienced by students of electron optics. Thus, a single consistent set of practical units is used throughout. The authors perhaps carry discretion too far in not mentioning what the system is and also in expunging from this edition any mention of alternative systems including SI. This together with the indiscriminate use of the symbol μ (surely a printer's error?) both for the permeability of free space and that of ferromagnetic materials may temporarily confuse the unwary. Strangely enough, the word permeability does not occur in the index, probably the weakest part of the present volume. The general treatment of the subject, however, is highly praiseworthy. Important concepts such as vector potential are first defined mathematically and then interpreted physically.

Likewise, in order to direct attention to the essential steps in the argument, simple, even clumsy, mathematical symbols have been preferred to more elegant but elusive shorthand notation. The mathematical treatment is designed to appeal to experimental physicists rather than to mathematicians and is closely interwoven with experimental results and illustrative material.

All important topics are covered, some in greater detail than others. An extensive and well arranged bibliography directs the curious to the appropriate source material. The book can, therefore, be strongly recommended to students, young and old, of electron optics and indeed as a work of reference to all who are engaged in research and development in electron optics.

T. MULVEY

Introducing Information

Introduction to Information Science. Compiled and edited by Tefko Saracevic. Pp. xxiv+751. (Bowker: New York and London, 1970.) $27.50.

INFORMATION science is a name that might be applied to many areas of study related to information theory in the Shannon–Weaver sense, as well as to information processing by computer. In recent years, several university postgraduate schools have coupled the words with librarianship, to imply what has also been called documentation, but the content of this teaching is still principally the art and practice of organizing documentary records of all kinds, and it might seem presumptuous to claim that this could be called a science.

This book aims to demonstrate that beyond the pragmatic arts of information organization, there is emerging an academic discipline that is objectively concerned with an area of human activity—communication processes particularly as they are mediated by information systems. Information is generated from a myriad of sources, often in documentary form, and it is sought by a myriad of users. The two streams merge in a complex network of information systems. The study of the structure, objectives, functions, properties, behaviour and performance of information systems and of their individual components (human or inorganic) is the emergent field of "information science".

There is as yet no formal textbook of the subject. The book under review is a collection of sixty-six papers by leading investigators, published mostly during the past decade. The papers are almost exclusively theoretical or experimental, and do not include pragmatic descriptions of the development or operation of information systems. The claim that the book "introduces" information science is justified by skilful editorial organization and comment that aims to display the content of and interrelationships within the science. As structured by Saracevic, the field covered includes communication processes (interrelationships exhibited by the documentary record and the behaviour of information users), the structure and attributes of information systems and procedures, and the evaluation of systems. The final paper is an attempt to outline a general theory of communication, by W. Goffman.

Information science has become quantitative and experimental. There is a good deal of mathematical modelling in these papers, and the development and use of system performance measures. There is also much descriptive analysis of the structure of knowledge, of information use and so on. That a recognizably distinct discipline has emerged is clearly demonstrated, though it is also clear that it is still a very young science. Its object of study is a social relationship (communication) achieved through physical media (such as books or computers), and this complexity accounts for the peculiar difficulty of placing it in any traditional "system of the sciences".

The selections brought together by Saracevic do represent the most thoughtful and stimulating work that has been done in this new field, though it is of course easy to regret the absence of significant papers. The book should indeed serve to "introduce information science" to workers in related fields, and be a useful source for students. Unlike many books of "readings", it makes a real contribution to the development of its subject.

CORRESPONDENCE

Aid for Bengal

SIR,—I feel that the letter by K. C. Tripathi (*Nature*, **232**, 69; 1971) does not do due justice to the splendid humane effort that India has exerted in the past (and present) Bengal crisis. It is all too easy, sitting in an economically and socially cosy island some 5,000 miles from Bengal, to decry the efforts of the Indian authorities in their troubles. K. C. Tripathi should try to visualize 6 million Pakistani refugees suffering from disease and starvation swarming across the Oxfordshire border and having only the resources of the Oxfordshire County Council to organize the relief aid, to appreciate just how stupendous would be the task of helping the refugees.

It is a fairly simple matter for the "developed" countries to send a few spare planes loaded with surplus stores and medicines and then to expect someone else to do the dirty work of organizing the distribution of the relief aid dumped on their doorstep.

The people of India have made a huge sacrifice in relation to their gross national product and their generosity and humanity should be laudified and not decried.

Yours faithfully,

P. J. S. BROOKS

Obituaries

Professor I. Vincke

IGNACE VINCKE, the eminent Belgian malariologist, died in Antwerp on March 13 at the age of sixty-five. He was born in Bruges where the family had long been established; his grandfather was Burgomaster and his father carried on the traditional occupation of growing bay trees for princely estates in Germany and the Low Countries. Ignace himself inherited "green fingers" and as a medical student he was awarded a Royal Medal for his discovery of a method for the sterile cultivation of orchid seeds. He graduated in medicine at the University of Ghent and, after taking the course in tropical médicine at the Institut Prince Léopold in Antwerp, embarked in 1931 for the Belgian Congo.

The starting point of Vincke's career was the study of the African anopheline mosquitoes; amongst which was *Anopheles dureni*, as the assistant of Albert Duren. He discovered sporozoites of a malaria parasite in this mosquito and for 5 years sought in vain the vertebrate host, which was clearly not man as the infected specimens were caught in uninhabited forest. In 1948 he traced the parasite to an arboreal rodent, *Grammomys surdaster*; he inoculated the blood into mice and rats and isolated a strain (*Plasmodium berghei*) which quickly became adapted as a model for the study of malaria in small laboratory animals. Within a year, the parasite was distributed throughout the world, and proved so useful that more than a thousand scientific papers have been written about it.

Strangely enough, Vincke's own interests veered from this discovery to the more pedestrian though more humanitarian pursuits of malaria control and eradication. But he continued his observations on the blood parasites of sylvatic rodents, and isolated another malaria parasite which was named *P. vinckei* in his honour, and a piroplasm which he named *Babesia rodhaini* in honour of his famous teacher, and both these organisms have been widely used in parasitological research. He worked on these problems, first in the Congo, then on various World Health Organization assignments and finally in the Department of Malariology in the Tropical Institute in Antwerp. His entomological interests remained and, as a result of his deep knowledge of the bionomics of mosquitoes, he was able both to apply DDT with intelligence in the rural zones of tropical Africa to destroy mosquitoes and to establish highly successful colonies in his insectaries in the Institut pour les Recherches Scientifiques en Afrique Centrale, and in Antwerp.

Vincke had a curious, unconventional personality. He loathed officialdom and once said, after a particularly frustrating period in the Congo, that "the only good DMS is a dead DMS"! He was quiet though mischievous (the late Professor Jacques Schwetz, also of the Congo Service, described him as a "méchant enfant"), charming and yet withdrawn, but with above all a great sense of modesty. The grand maître of Belgian tropical medicine, Jerôme Rodhain, appreciated the unusual talents of his pupil and foresaw a great future for him. His eminence was recognized with various awards, including the Prix Broden from Belgium and the Prix Carlos Chagas of Brazil, and by his elevation as Commander in the Order of Léopold.

Academician V. V. Parin

ACADEMICIAN Vasilii Vasilevich Parin, one of the leading physiologists and experts on space medicine in the Soviet Union, died on June 15, 1971.

Parin was born in 1903, in Kazan'. He graduated in 1925 from the Medical Faculty of Perm University and from 1930 to 1947 he held the post of head of the Department of Physiology at institutes in Perm, Sverdlovsk and Moscow. From 1942 to 1945 he was Deputy People's Commissar of Health of the USSR, and in 1944 he became a founder member and first Academic Secretary of the Academy of Medical Sciences of the USSR.

His academic career was interrupted in 1947, when he was imprisoned in a labour camp. After his release in 1954 he became head of the Physiology Laboratory of the Institute of Therapy of the Academy of Medical Sciences. Later appointments included head of the Faculty of Clinical and Experimental Physiology of the Central Postgraduate Medical Institute, director of the Institute of Normal and Pathological Physiology of the Academy of Medical Sciences, director of the Institute of Medico-Biological Problems of the Ministry of Health of the USSR, director of the Laboratory of the Control of Functions in Human and Animal Organisms of the Academy of Sciences of the USSR, and deputy academic secretary of the Department of Physiology of the Academy of Sciences. He was closely associated with the Soviet space programme from the earliest launches of rockets bearing test animals, and is understood to have been one of the principal organizers of the medical and biological experiments in the space programme.

He was on the editorial board of several physiological and medical journals and he published over 200 scientific and popular works on the regulation of blood circulation and space physiology and cardiology. He was also a member of Soviet delegations to a number of international conferences, a member of the International Astronautics Academy and an honorary member of the Rumanian

Academy of Sciences and the Purkinje Czechoslovak Medical Society. The awards he received included the Order of Lenin and the Order of the Red Banner of Labour.

Announcements

University News

Dr J. B. Lloyd, University College, Cardiff, has been appointed research professor in biochemistry in the **University of Keele.**

Dr Peter Harris has been awarded a personal professorship in the Department of Earth Sciences, **University of Leeds.**

The title of professor of physics has been conferred on **Dr P. V. March** in respect of his post at Westfield College, **University of London,** and that of professor of pathology has been conferred on **Dr T. Symington** in respect of his post at the Institute of Cancer Research, Royal Cancer Hospital.

Miscellaneous

The first **Florey fellowship** has been awarded to **Dr G. G. MacPherson,** MRC junior research fellow at the Sir William Dunn School of Pathology, University of Oxford, to enable him to work for two years on the physiology of the lymphatic system and its role in transplantation immunity, at the John Curtin School of Medical Research, Australian National University.

Bruno Mendel travelling fellowships have been awarded by the Council of the Royal Society to **Mr C. M. Colley,** University of Cambridge, and to **Miss M. Small,** Weizmann Institute of Science. Mr Colley will study the interactions between lipids and proteins in cell membranes at the State University, Utrecht, and Miss Small will work at the Chester Beatty Research Institute on the interaction between a lymphocyte activator from thymus and its possible target cells.

The Fondación Viviana Luckhaus international prize will be awarded in 1972 for a paper describing original research work related to blood platelets and/or their relationship to thrombosis and blood vessels. The prize will consist of an award of 18,188 Lay (3,000 dollars), a medal and a ticket and expenses for a one-week trip to Buenos Aires, and is open to investigators of all nationalities. Further information can be obtained from Dr Jorge Buraschi, Fondación Viviana Luckhaus, Hospital Juan Fernandez, Cerviño 3356, Buenos Aires, Argentina.

International Meetings

September 11–26, **Swiss National Autumn Fair,** Lausanne (Association des Intérêts de Lausanne, Rue Chancrau 3, Lausanne, Switzerland).

September 28–October 2, **Europrotection,** Paris (Europrotection, 8 rue de la Michodière, 75 Paris 2e, France).

September 29–October 1, **Research and Development,** The Hague (Financial Times Conference Department, 338 Strand, London WC2R 0LT).

October 4–6, **Turbulence in Liquids,** Rolla (John Short, Continuing Education, University of Missouri-Rolla, Rolla, Missouri 65401, USA).

November 24, **Computer aided Microscopy,** London (Meetings Officer, Institute of Physics, 47 Belgrave Square, London SW1).

NATURE Volume 232 JULY 30 1971

Responsibility without Government

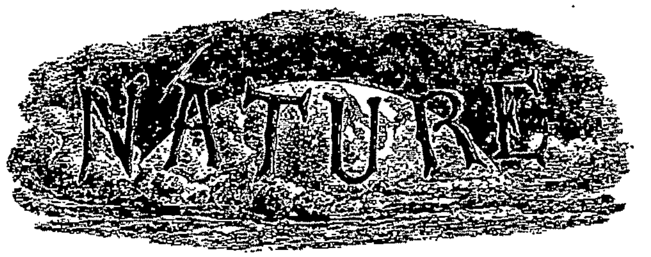
THE Select Committee on Science and Technology is entirely within its rights to complain, as it did on Wednesday, that the government is dragging its feet on planning for the future of research and development in Britain. In what appears to be a yearning for unattainable perfection, the British Government appears bent on resolving to its own satisfaction and in theory all possible questions before it actually sets out to tackle any one of them. The result is that the report of the committee under Sir Frederick Dainton on the reorganization of civil research, which has already been discussed by the Council for Scientific Policy —its legitimate parent—and passed on to Mrs Margaret Thatcher at the Department of Education and Science, has disappeared into never-never land. Would-be recorders of events have to be satisfied with such straws in the wind as they can find. Does, for example, the fact that the government has made an appointment for only one year as Secretary of the Agricultural Research Council imply that it expects a major reorganization within the year? Time may yet tell, but in the meantime uncertainty persists about the future of the research councils and their relationship with each other, with government departments concerned with specific functions and with the universities especially, because even a rapturous acceptance of the Dainton report would be unlikely radically to transform the functions which research councils at present undertake. There is no need for such a revolution but there is a sense in which procrastination creates problems out of nothing.

The select committee is also entirely right to protest at the way in which the government has done nothing to remove uncertainty, or even to make fuller use of the resources which exist, in the wider context of how civil research as a whole should be undertaken. The Atomic Energy Authority remains in a kind of limbo, with Aldermaston still within the civil field in spite of the near-certainty that it will eventually become a defence laboratory, with the laboratory at Harwell ploughing ahead so successfully at commercial developments of various kinds that it sits increasingly uncomfortably beneath the umbrella of atomic energy, and there is persistent uncertainty not merely about government policy about institutions such as the research associations but towards the whole principle of how and when governments should intervene in industrial research. It may be true, as the government appears to have decided off its own bat, that the time has come for a thoroughgoing review of policy on research. After all, it is now seven years since the report of the Trend committee advocated institutions for regulating the relationship between industry and government on research which have not for practical purposes been taken up (although there is an echo of them in Mr Anthony Wedgwood Benn's now defunct Green Paper on industrial research). It is also true that the issue is important enough to justify a philosophical and measured solution. The question is merely whether industrial research and development can wait that long—and also whether the problem will be the same a year from now.

By all accounts, responsibility for the new policy lies with Lord Rothschild. At the outset, the Council for Scientific Policy seems to have been fully informed of the status of the Dainton study and in particular of the intention that this should be merely one of several ingredients of a much fuller appraisal of present problems. One of the anxieties now is that a worthy piece of work should be not merely subsumed in a larger study but even made the basis for policy decisions which are put into effect without public discussion in advance. Yet all the experience of the past few decades has made it perfectly plain that juggling with the institutions of the scientific establishment, necessary though it may be, is possible only if the institutions concerned and those who work in them have had a chance to say their piece. On many occasions, the government of the day has been saved from error by precisely such discussion. It would therefore be a token not merely of good intentions but of good sense if the government were now to sanction the publication of the Dainton report. That would be something to be going on with. (At the same time, the Council for Scientific Policy could help its own case for public discussion by helping to ensure that the research councils under its own wing were more forthcoming with the publication of documents of public importance—the report on astronomy in the northern hemisphere which the Scientific Research Council has commissioned (see page 289) should, for example, be published without delay).

---

100 Years Ago



How, then, did life originate on the Earth? Tracing the physical history of the Earth backwards, on strict dynamical principles, we are brought to a red-hot melted globe on which no life could exist. Hence when the Earth was first fit for life, there was no living thing on it. There were rocks solid and disintegrated, water, air all round, warmed and illuminated by a brilliant Sun, ready to become a garden. Did grass and trees and flowers spring into existence, in all the fulness of ripe beauty, by a fiat of Creative power? or did vegetation, growing up from seed sown, spread and multiply over the whole Earth? Science is bound, by the everlasting law of honour, to face fearlessly every problem which can fairly be presented to it. If a probable solution, consistent with the ordinary course of nature, can be found, we must not invoke an abnormal act of Creative Power. When a lava stream flows down the sides of Vesuvius or Etna it quickly cools and becomes solid; and after a few weeks or years it teems with vegetable and animal life, which for it originated by the transport of seed and ova and by the migration of individual living creatures. When a volcanic island springs up from the sea, and after a few years is found clothed with vegetation, we do not hesitate to assume that seed has been wafted to it through the air, or floated to it on rafts. Is it not possible, and if possible, is it not probable, that the beginning of vegetable life on the earth is to be similarly explained?

OLD WORLD

SCIENTISTS' PAY

Protests Galore

THE series of meetings organized by the Institution of Professional Civil Servants (IPCS) to publicize the current salary dispute between the British Government and the scientists in its employ is now almost over but the climax is yet to come at the Central Hall, Westminster, on August 10. The support obtained so far has at least demonstrated that government scientists are wholeheartedly behind the IPCS. Whether their anger will be productive remains to be seen.

After the disagreement between the institution and the government, an arbitration tribunal is being set up under the chairmanship of Mr M. J. Mustill, QC. This will sit on August 12 and possibly August 13. A minor success for the institution has been to reverse the original decision to hold the tribunal *in camera* and the proceedings will now be relayed from Abbey Gardens, NW8, to the nearby Bishop Partridge Hall, which the institution hopes to fill with its members.

The final meeting at Central Hall is to be addressed by Dr Harold Turner, of the National Physical Laboratory, Teddington, who is chairman of the institution's Scientific Task Group, and by Mr William McCall, the General Secretary, with Mr J. C. McGloughlan of the IPCS in the chair. The institution is hoping for an overwhelming show of support but at the same time it is not giving any encouragement to the notion being circulated in government laboratories that everybody should take half a day's leave on August 10 in order to attend the meeting—thus effectively bringing all work to a halt on that afternoon. This would violate the promise already given by the IPCS that it would not resort to industrial action to achieve its claims.

A spokesman said earlier this week that the institution is quite optimistic that the outcome of the tribunal will bring a better offer than that already made. The government's view, however, is restated in a letter from the Prime Minister to Mr Airey Neave, the Member of Parliament for Abingdon, who has been taking a close interest in the scientists' claim. Mr Heath has refused to intervene in the dispute and has reiterated that the government had considered all the arguments advanced by the IPCS after it received the first pay offer, but in its view these arguments did not "justify any improvement in the offers that have been made".

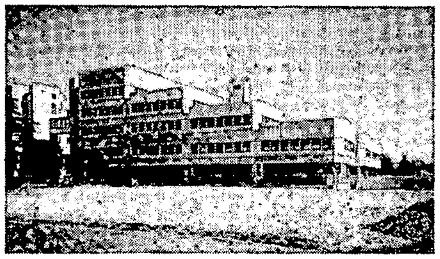
A matter of concern to the scientists is the apparent downgrading of their profession compared with other classes in the Civil Service, in particular the administrative grades who received a salary increase earlier this year. The institution's fear is that there is discrimination against the scientists but Mr Heath states that there is no question of this and "continued progress in science and technology is essential to the future of this country, and the government attaches great importance to the contribution made by the scientific staff within the Civil Service". It is doubtful whether this will mollify the scientists at this stage as the hard facts of the government's offer do not bear out Mr Heath's statement.

Whatever the outcome of the tribunal, the IPCS must consider whether the mechanism at present used to determine salaries within the Scientific Civil Service is the most appropriate. There is no doubt that in view of the latest experience most scientists would prefer not to have their salaries determined as a result of a pay research exercise but some method must be used that will ensure parity with salaries both inside and outside the Civil Service.

BIOLOGY

Old and New at Oxford

OXFORD'S biologists seem to have been celebrating with gay abandon recently. Two weeks ago, the zoologists and psychologists heralded the opening of their new palatial building and on July 24 the Botanic Garden was toasted with champagne on the occasion of its 350th anniversary.



Part of the laboratory built in Oxford for the departments of zoology and psychology. (Photo: Surveyor to the University.)

The garden was founded by Henry Danvers, Earl of Danby, who gave it walls strong enough to withstand the siege of the Civil War and remain unharmed through the succeeding centuries. Many distinguished botanists have tended the plants and worked at their scholarly pursuits within the walls. Although the Professor of Botany no longer personally superintends the activities of the garden, he is still its official keeper, and last week Professor C. D. Darlington, fulfilling one of his last functions before retiring next September, welcomed the Chancellor of Oxford University, Mr Harold Macmillan, and the guests who had braved the rain to join the celebration. The chancellor marked the occasion by planting a specimen of the scholar tree, *Sophora japonica*.

Among the non-botanical guests on this occasion were Professor J. W. S. Pringle of zoology and Professor L. Weiskrantz of psychology, who recently moved into their new building which was opened by Professor A. L. Hodgkin on July 12. The building, which cost £2 million, was designed by Sir Leslie Martin to bring together two departments which were previously scattered around Oxford. Now they occupy two sides of a complex which is linked by a spine housing common facilities such as libraries and lecture rooms. The furniture and fittings are sumptuous—the workbenches are made of teak; there are two electron microscopes on independently suspended floors; the zoology department is wired for closed circuit television. There is even a tropical climate room.

Brackish Water

THE committee that was set up last year to form an Estuarine and Brackish-Water Biological Association in the United Kingdom has announced plans for the association's inaugural symposium to be held at the Zoological Society of London on October 13, 1971. The need for such an association arises from the varied disciplines of the scientists who are interested in the properties of these waters and so the association will enable people working in such diverse fields as biology and sedimentology to have a common platform. Future plans for the association include regular meetings and the publication of a bulletin.

The committee feels that the essential unity of aquatic science can best be served by emphasizing the function of the previously neglected estuarine sector so that a bridge can be built between the freshwater and marine fields. The formation of the association will then be an important step towards the eventual integration of outlook for these disciplines.

The inauguration of the association will take place during the meeting in October. Membership will be open to anyone but the feeling of the committee is that it will probably be most attractive to research workers in appropriate fields.

ASTRONOMER ROYAL

New Astronomy

A NEW twist occurred last week in the search for a new Astronomer Royal with the announcement that the post is to be dissociated from the directorship of the Royal Greenwich Observatory. This move will please those who have been arguing for just such a break between the two jobs, which will take effect at the end of the year, with the retirement of the present Astronomer Royal and director of the Royal Greenwich Observatory, Sir Richard Woolley.

Now that observational astronomy is no longer the prerogative of optical observatories, the argument goes, it is anachronistic to insist that the Astronomer Royal should also be equipped to manage the optical telescopes associated with the Royal Greenwich Observatory. Indeed, as one astronomer has remarked of the quest for a suitable replacement that has been going on since Sir Richard's retirement was announced a year ago, logically there ought to be astronomers royal for X-ray and radio as well as optical astronomy, a post which, it has been suggested, might have the title of Master of the Queen's Astrophysik.

Such tongue in cheek proposals during the past year have, however, gone hand in hand with real concern that the best decision be made about the role of the Astronomer Royal and of the Royal Greenwich Observatory. One view has been that the post of Astronomer Royal should die when Sir Richard Woolley retires, but most astronomers would probably prefer to keep the old name, either linked to the Royal Greenwich Observatory or as an honorary title that can be held by any British astronomer, perhaps for a set period only.

Whether last week's announcement will make any easier the task of finding a successor to fill Sir Richard Woolley's second role as director of the Royal Greenwich Observatory is a debatable point. The overt explanation for separating the two posts is that it throws open the directorship to foreign astronomers—the Astronomer Royal cannot be non-British, although oddly enough the post of Astronomer Royal for Scotland has only once been held by a Scot. But Sir Brian Flowers may now find that some potential candidates will be discouraged by what amounts to a downgrading of the post. It is believed that a Dutch astronomer has already been unsuccessfully approached.

More important than the personality of the next Astronomer Royal, however, is that this watershed is being taken as an opportunity for a reappraisal of British astronomy. The time is particularly appropriate, for during the next few years many of the grand old names of British astronomy will reach retiring age, so that several crucial chairs will become vacant. To the extent that the Science Research Council can influence appointments within the universities, decisions taken during the next few years will affect British astronomy for several decades. Traditionally the Royal Greenwich Observatory has been at the heart of British astronomy, but since the war the new branches of astronomy that have developed outside the Royal Observatory system have called into question the wisdom of giving such a prominent role to an organization that was established primarily to provide astronomical information for mariners. This question came to a head a year ago when the Science Research Council was handed a review of the future of astronomy in the northern hemisphere that it had commissioned from a group of scientists that included astronomers, a space scientist, a nuclear physicist, and the two astronomers royal. As usual the report is being treated in a typically close-handed way by the Science Research Council, and is now unlikely to be published.

It is, however, understood that the most contentious proposal is that a British observatory to be established in the Mediterranean area be managed not by the Royal Greenwich Observatory, but by a new institution that would be linked with a group of universities. An association similar to the federation of ten universities that manages the Kitt Peak observatory in the United States is what the review committee had in mind, and is thought to have been accepted by all members of the committee with the exception of the two astronomers royal.

Although on paper at least the Royal Greenwich Observatory does not have control of the only large telescope that is available to British astronomers—the 98-inch Isaac Newton telescope—or the 150-inch telescope that is being built as a joint venture with the Australians, there seems to be a widespread feeling that the observatory exerts an influence on the running of the telescopes that is inimical to the progress of British astronomy.

In any case, the staff at the Royal Greenwich Observatory saw how the wind was blowing as long ago as November 1968—before the northern hemisphere review began in earnest—when all the scientific staff of the observatory signed a petition to the Queen to seek assurances that the directorship of the observatory would continue to be linked with the post of Astronomer Royal. At about the same time, Sir Brian Flowers wrote to the staff at the observatory saying that the staff would be consulted if there were any proposal to dissociate the directorship from the post of Astronomer Royal, a promise which the Institution of Professional Civil Servants says has not been kept.

In other words, the staff of the observatory are rightly concerned that the announcement last week marks the beginning of a downgrading of the observatory. The staff expect the first consequence to be that greater difficulty will be experienced in finding a strong candidate for the directorship. But at the backs of their minds is the fear that the Science Research Council will encourage the Royal Greenwich Observatory to become a service organization, at the behest of the universities.

Views on the appropriateness of such a future for the observatory depend on what attitude is taken to the usefulness of scientific institutions that are divorced from the universities and from industry (although the staff of the observatory will point to their strong links with the vigorous astronomy department at the University of Sussex). But for the time being at least, the plan to set up a new institution linked with a number of universities appears to have been shelved, apparently because of the cost although this is thought to have been modest. On the face of it, then, the present arrangements for managing the large optical telescopes will continue. Nevertheless, the next director of the Royal Greenwich Observatory will have to be prepared for criticism of the establishment from many astronomers who see the observatory as a white elephant. In particular, the £1.2 million which the Science Research Council spends on the Royal Greenwich Observatory, the Royal Observatory at Edinburgh, and on the observatories in South Africa is widely held to give poor returns compared with the running costs of the Hale Observatories of $1.7 million per year. In addition, the siting of the 98-inch Isaac Newton telescope adjacent to the Royal Greenwich Observatory a mile or so from the Sussex coast is still felt to be the most short-sighted decision in the management of British astronomy. The small amount of astronomy that it has been possible to carry out with the telescope compares unfavourably with the productivity of the Hale Observatories, for example, and many astronomers would be happy to see the telescope moved to the Mediterranean area at the first opportunity. It is true that there is little hope now that a site can be found in the Mediterranean that will produce the rapturous praise that astronomers reserve for the skies of Chile, but almost anywhere, the saying goes, will be better than Sussex.

NEW WORLD

AEC Bruised but not Cut

by our Washington Correspondent

AFTER the Food and Drug Administration, the Atomic Energy Commission probably ranks second in the list of the most heavily criticized federal agencies. During the past year it has had to face a barrage of criticism from environmentalists who oppose extension of the nuclear power programme, its safety procedures have been thrown into disrepute by a series of failures under test of the emergency core cooling device, and it has lately been placed in a compromising position by its advocacy of the nuclear test planned to take place in Alaska in the autumn.

This outspoken public disenchantment with the AEC's plans has not, however, gained a footing in Congress, for only last week both houses agreed to authorize more funds for the AEC than were requested in its budget, and only a few minor programmes have been trimmed by the Joint Committee on Atomic Energy which recommended the authorizations to Congress. Although the authorizations represent only the maximum funds that can be appropriated for the commission—its budget must now be considered by the Appropriations Committee—it seems likely that the AEC will be able to proceed with all the major parts of its planned programme for 1972.

The authorizations passed by Congress amounted to just over $2,321 million, $37 million more than the commission requested, and essentially the same amount as authorized for 1971. Chief beneficiaries of this Congressional largesse are the programmes for nuclear space propulsion (the Nerva rocket programme) and gaseous diffusion technology, which were increased by $37 million and $31 million respectively. The Joint Committee on Atomic Energy has, however, docked $21.5 million from the AEC's request for funds to establish a radioactive waste repository at Lyons in Kansas, and cut by half the commission's request for $1 million to develop a nuclear powered cardiac pacemaker, although the full amount was later restored by an amendment which was proposed in the Senate by Hugh Scott, the ranking Republican from Pennsylvania.

The joint committee left untouched the $263.6 million requested for physical research, although it has a cautionary word to say to the high energy physics laboratories operated by the AEC. When the 200 GeV accelerator at the National Accelerator Laboratory in Illinois becomes fully operational, it will require an annual funding of between $60 and $70 million which is more than half the $116 million requested for the whole high energy physics programme for 1972. The joint committee therefore asks the AEC to "examine the minimum level of support necessary to keep each of its high energy accelerator laboratories, including the NAL, viable and productive, and that it develops a priority listing of which accelerators should be kept operating should future funding be less than the minimum necessary to effectively support each of the six laboratories". The AEC has been asked to furnish the joint committee with its priority listing by the end of 1971.

Following the lead of the Senate Committee on Aeronautical and Space Sciences and the House Committee on Science and Astronautics, the Joint Committee on Atomic Energy has restored in full the funds requested for development of the Nerva nuclear powered rocket. In its budget request to the Administration, the AEC asked for $52 million for research and development on Nerva, but this was slashed by the Office of Management and Budget to $15 million—barely sufficient to keep the project ticking over, and probably a sufficient reduction to kill the project altogether.

What impressed the joint committee most was a series of joint hearings conducted with the Committee on Aeronautical and Space Sciences in February, during which a series of witnesses testified that the Nerva programme has so far been successful and is up to schedule. The joint committee therefore proposed, and Congress agreed without criticism, that the AEC should get the full $52 million requested, and that this should be split into $35.2 million for rocket propulsion development, $13.8 million for advanced research and development, and $3 million for operation of the Nuclear Rocket Development Station in Nevada (the Administration had deleted all funding for this latter facility).

The joint committee also looked favourably on Project Plowshare—the proposal to excavate natural gas by nuclear explosives. Congress last week authorized $8.1 million for this project—an increase of $3.1 million on the Administration's request. The idea is to use nuclear explosives to release natural gas from underground deposits more cheaply than by conventional means, but this proposal has already fallen foul of many sectors of opinion. Dr John Gofman, an ardent critic of the Atomic Energy Commission, for example, said last week that he regards the decision to proceed with Plowshare as "extremely unfortunate". Pointing out that "all these programmes eventually end up spewing radioactivity into the atmosphere", Gofman said that the concept that natural gas can be excavated by nuclear explosives and pumped into people's homes along with some radioactive debris is "so grotesque that we should have abandoned this project long ago".

The AEC estimates that Project Plowshare can bring natural gas to the consumer pipelines within five years, at an estimated government cost of $50 million, and to this end it proposes to test a device in 1972. If successful, it has been estimated that the project will double the nation's natural gas reserves, and apart from the economic advantages of such an achievement, its supporters justify Plowshare on the grounds that it will provide the market with a largely pollution-free fuel. But that justification would be something of a mockery if the project ended up contaminating the atmosphere with radioactivity, and if it also provided natural gas contaminated with radioactivity.

The joint committee has, however, sounded a more cautionary note in its deliberations on the AEC's proposals for the long term storage of radioactive wastes. The kingpin of the AEC's programme is to store such wastes in a disused salt mine in Lyons.

Kansas, and the commission requested $25 million for acquisition of land and for construction of facilities. But the joint committee has slashed this request by $21.5 million. In spite of a report by the National Academy of Sciences, which concluded that the use of bedded salt deposits represents the safest disposal method now available, the joint committee has taken the sensible step of requiring that the AEC makes further studies of the safety of the mines before they are acquired for use. In particular, the joint committee has asked for more information on heat transfer between the salt/shale interface, areal hydrology and geology, possible environmental damage, the transportation of waste to the salt mine and waste retrieval after burial. The AEC has, however, stated that such questions cannot be answered until small amounts of waste have been deposited in the mine, but that argument cut no ice with the committee, which stated in its report to Congress that "all reasonable questions raised must be answered from the standpoint of satisfying Kansas and Federal officials *before the Lyons facility is put into operation as a respository for industrial wastes*". (Committee's italics.)

The most controversial item in the AEC authorizations is the $19.7 million requested for the testing of a nuclear weapon in an underground site on Amchitka Island in the Aleutians off the coast of Alaska. The reason for the test, which was explained by the AEC in full only a day or so before the Senate debate on the authorizations, is to monitor the X-ray spectrum produced by the warhead of the Spartan anti-ballistic missile (the longer range missile that forms part of the Safeguard system). A statement sent by the AEC to Senator John O. Pastore, chairman of the Joint Committee on Atomic Energy, pointed out that the kill mechanism of the Spartan missile is X-rays released outside the atmosphere, and that this requires a low fission output so as to minimize radar blackout, and a high X-ray output.

The AEC therefore uses a mixture of economic, scientific and pragmatic justifications for the test. It says, for example, that failure to conduct the test would drastically reduce confidence in the missile, and that the test is necessary "to minimize the possibility of stockpiling a defective design", to measure the fission output, and to monitor the X-ray flux and yield. If the test does not take place, the AEC points out, "one would be forced to rely on theoretical calculations to determine X-ray flux and spectrum without the benefit of any meaningful experimental data".

Code-named Cannikin, the test is due to take place in October. With a yield of five megatons, it will be the largest underground explosion ever conducted by the United States, and it has already sparked off a wealth of political and scientific criticism. But amendments to the Authorizations Bill, introduced in the House by Mrs Patsy Mink, and in the Senate by Senator Mike Gravel, failed to prevent funds being authorized for the explosion, and the chief hope now is that President Nixon will veto the programme. Opposition centres around four chief points: that the test will release radioactive debris into the atmosphere directly through venting, and later by seepage of ground water; that the explosion may trigger an earthquake which could cause a tidal wave, resulting in substantial damage along the Pacific coast; that it could sabotage the Strategic Arms Limitation Talks (SALT) now taking place between the United States and the Soviet Union in Helsinki, and that in any case development of the Safeguard ABM system is likely to be a destabilizing influence on the arms race.

As far as the environmental consequences of the test are concerned, the AEC has consistently underplayed the likely effects of Cannikin. To be sure, even critics of the test acknowledge the fact that dire environmental consequences are a remote possibility, but they also point out that as long as the possibility exists the test should be scrapped. The most publicized risk involved in the test is that it may trigger off a massive earthquake in the region which could in turn cause a tidal wave, with devastating consequences for the Pacific islands, and even for California and other parts of the US Pacific coastline. The Aleutian islands are a particularly active earthquake area, and it has been estimated that the Cannikin blast will be equivalent to an earthquake of magnitude 7 on the Richter scale. (By comparison, the quake which shook California earlier this year was rated at 5.9.)

In an environmental policy statement which the AEC was required to publish under the terms of the National Environmental Policy Act of 1969, however, the commission stated "experience gained by observation of past nuclear detonations and earthquakes combines to provide extremely positive assurance that the Cannikin explosion cannot of itself cause a severe earthquake". But an *ad hoc* panel of scientists headed by Dr Kenneth Pitzer, which met under the auspices of the Office of Science and Technology in 1968, took a less rosy view of the situation. Its report stated: "There does not now appear to be a basis for eliminating the possibility that a large test explosion might induce, either immediately or after a period of time, a severe earthquake of sufficiently large magnitude to cause serious damage well beyond the limits of the test site. This possibility is more serious for tests greater than a megaton. . .". It has also been suggested that there is a one in a hundred chance that an earthquake bigger than the Cannikin blast will occur in the Aleutians in any two week period. What would happen if such an earthquake occurred simultaneously with the Cannikin test is a moot point.

Two underground tests conducted at the Nevada site have also been found to release more than ten times the energy released by the blasts themselves. But the Pitzer report pointed out: "Since the Amchitka area in Alaska is still more active seismically, the hazard of inducing an earthquake must be considered to be greater at that location than at either Nevada site." One point that the AEC emphasizes, however, is that the Milrow test—a one megaton "proving" test for the Cannikin blast, conducted at Amchitka in 1969—did not produce any sizable aftershock.

As far as leakage of radioactive debris is concerned, one fear which was suggested last week by Dr Robert Fleisher, director of the Committee for Nuclear Responsibility, is that if massive venting does occur (and some of the Nevada tests have resulted in quite large venting), radioactive fallout could be carried outside United States territory, in violation of the partial test ban treaty. There is also a fear that if there is an unsuspected fault close to the test site, leakage of radioactive material through groundwater could occur relatively quickly, resulting in danger not only to the wildlife in the Northern Pacific, but also to the Alaska coast. And this fear is intensified by suggestions that the Cannikin blast could also release radioactive debris remaining from the Milrow test. The AEC's environmental policy statement suggested, however, that "it is not conceivable that Cannikin would cause release of underground radioactivity from the cavities which remain from the earlier Milrow and Long Shot tests". Unfortunately, however, that statement was not accompanied by any discussion of why such a possibility is inconceivable.

In view of these serious doubts about the safety of the test, the Committee for Nuclear Responsibility, whose board of directors contains the names of James Watson, John Gofman, Paul Erlich, Linus Pauling and George Wald, has filed a suit against the Atomic Energy Commission, in an attempt to stop the test. Dr Robert Fleisher, executive director of the committee, said last week that the National Environmental Policy Act requires that if a project involves the possibility of serious ecological damage, it must be proved to fulfil an enormous need. He charges that the AEC's environmental policy statement does not provide such evidence, and that will be the basis of the committee's court action.

The most likely possibility for stopping the test rests, however, in its political repercussions. For one thing, it could seriously damage the chances of success in the SALT talks, which according to recent reports are progressing along hopeful lines. It has been suggested, for example, that the United States has proposed verbally, and will later propose in writing, an agreement that would halt the construction of both land-based and sea-based missiles, and also that as many as 300 missiles would be allowed in the US and the USSR to protect offensive missile sites. For President Nixon to cancel the Cannikin test would therefore help to establish his credibility in his desire to curb the arms race.

But a more immediate factor is the Presidential elections in 1972. Now that the possible consequences of the Cannikin blast have been aired in the press and in Congress, Nixon could well put off the test until after the 1972 campaign. If he in fact decided to go ahead on schedule, and an unlikely catastrophe did take place, his chances of re-election could be ruined. Some observers are very optimistic about the chances of a Presidential veto, and one critic of the programme suggested last week that the chances are "fifty-fifty or better". Another but less likely possibility is that the appropriations for the test could be deleted when they come up for debate in Congress. Senator Gravel is likely to oppose them in the Senate, and he will probably get more support then than he did last week when he proposed an amendment to the Authorizations Bill seeking to delay the test until after May 31, 1972. That amendment was defeated by a vote of 37 to 57, but with more exposure in the press, and if the SALT talks continue to progress towards a moratorium on the construction of nuclear weapons, Gravel may be able to muster enough votes, if not to defeat the appropriations outright, at least to provide Nixon with added justification for vetoing the measure.

FDA

New Name, Old Face

by our Washington Correspondent

If the Administration gets its way with Congress, the name of the Food and Drug Administration may soon be deleted from the list of Federal agencies, and in its place will be substituted the much more grandiose title of the Consumer Safety Administration. But this exercise in semantics will do little to appease the many critics of the way the FDA conducts its business, for instead of radical changes in the functioning of the FDA, what is being proposed is that it should have extra responsibilities grafted on to its present unsatisfactory structure. The proposal, in the form of a bill introduced into the Senate by the Administration, came under scrutiny by the Senate Commerce Committee last week, and it has also been given President Nixon's personal blessing.

The idea is that the FDA will cease to be solely a watchdog over food and drugs and that instead its responsibilities should extend over the whole field of product safety. This proposal was spelt out in some detail by Elliot L. Richardson, Secretary of Health, Education and Welfare, before the Commerce Committee last week. He said that when the bill is passed, "I propose to build upon the FDA framework by establishing a new Consumer Safety Administration to be composed of three major offices: the Office of Product Safety Regulation, the Office of Drug Regulation and the Office of Food Regulation." And, in a letter to Senator Frank E. Moss of Utah, chairman of the subcommittee considering the bill, Nixon left no doubt about the fact that the FDA will continue to operate in much its present form. After announcing his approval for the bill, the letter went on to say that "this unit (the proposed Consumer Safety Administration) will build upon the activities, personnel and facilities of the FDA, which has a long and distinguished history in the field of consumer safety".

The Administration's bill is a counter proposal to a bill introduced by Senator Moss and Senator Warren G. Magnuson which also seeks to extend the Federal Government's responsibility for the control of potentially dangerous consumer products (such as toys that are likely to cause actual bodily harm), but the essential difference between the two proposals is that the Moss–Magnuson bill seeks to set up a division of product safety outside the Department of Health, Education and Welfare. The chief idea behind such a measure is that the new agency could respond more readily to consumer interests if it were taken out of the bureaucracy of HEW, and it stems from a report published by the National Commission on Product Safety. Testifying before the Senate Committee on Commerce last week, David Elkind, Chairman of the National Commission on Product Safety, left no doubts about his dislike for the Administration proposal, calling the proposed Consumer Safety Administration a "paper tiger", Elkind said "the first step in creating a paralytic consumer protection function is to place it deep in the recesses of the already overburdened and unsuccessful Department of Health, Education and Welfare".

Why has the Administration chosen to oppose the Moss–Magnuson bill? Apart from the fact that to set up a unit outside the FDA may be regarded as the first step in dismantling the agency, the overt reason is one of administrative neatness. Richardson, for example, said that the FDA already has extensive laboratory and testing facilities, and that to set up a separate organization outside HEW may duplicate some of those facilities. He dismissed the idea, moreover, that an independent agency would be more receptive to consumer pressures than an expanded FDA, and came close to agreeing with critics of the FDA when he suggested, "I do not think that independent regulatory agencies have historically shown a greater resistance than other agencies to the pressures that often cause agencies to identify their interests with those of the industries they regulate".

If the Commerce Committee eventually decides not to go along with the Administration, but to support the Moss–Magnuson bill, the FDA would find itself in an embarrassing position, for Richardson confessed to the committee in reply to a question from Moss that he has already set up a division of product safety within the FDA, and Dr Charles Edwards, Commissioner of the FDA, later explained that in three to five years' time the Office of Product Safety would be the largest division of the FDA. He suggested that $19 million would be spent on setting up the new office in 1972, and that some of this money would be taken from the already undernourished and overburdened food and drugs offices.

According to Edwards, the new style FDA will parallel the Environmental Protection Agency in terms of function of operation, but Elkind was quick to point out that the essential difference between the two agencies is that the FDA will continue to operate from within the bureaucracy of the Department of Health, Education and Welfare, while the EPA was set up as an independent agency for the very reasons that the National Commission on Product Safety asked for an independent Consumer Safety Agency. The Administration's bill, he retorted, would "be as though the government were to fashion, like Dr Frankenstein, a man with beautiful sinews, long arms and piercing eyes, with just one weakness—an inability to hear from the consumer and respond to his needs".

NEWS AND VIEWS

X-Chromosome Inactivation in Mules and Hinnies

ACCORDING to the inactive-*X* hypothesis of dosage compensation (Lyon, *Nature*, **190**, 372; 1962), one or other of the two *X*-chromosomes of the mammalian female becomes genetically inactivated at an early stage of embryonic development and the choice of which *X* becomes inactivated in each cell is a random one, with the result that clones of cells arise within individual females, having either the maternally-derived or paternally-derived *X* in the inactive condition. The late DNA replication of one *X*, observed in the somatic cells of female mammals, and genetic inactivity of one *X* are generally considered to be related phenomena but as yet there is no final proof of this.

Horse–donkey hybrids have two qualities which make them unique material for testing the inactive *X* hypothesis: first, the horse and donkey *X*-chromosomes are morphologically distinguishable and, second, the *X*-linked genes which code for glucose-6-phosphate dehydrogenase (G6PD) in each species show different electrophoretic mobilities. A mixed expression of horse and donkey G6PD is generally found in cell cultures from female mules and hinnies but evidence that this derives from the presence of two cell populations, one with the donkey *X* active and one with horse *X* active, has only now been obtained. Hamerton, Gianelli and co-workers in an article on page of this issue of *Nature* have shown that cloning cells from original skin fibroblasts which show mixed G6PD expression yield clones which produce either horse or donkey G6PD. A small proportion of clones showing mixed expression were also found but, on recloning, these could again be broken down into the two component cell types. These data are thus consistent with the inactive-*X* hypothesis but, although they do not disprove Grüneberg's hypothesis (*J. Embryol. Exp. Morph.*, **22**, 145; 1969) that the activity of one or other *X* may range from 0 per cent to 100 per cent of the total *X*-chromosome activity of any one cell, they make it seem most improbable that such a mechanism operates in the mule, at least *in vitro*.

An impressive inverse correlation between late replication of the horse and donkey *X*-chromosomes and horse and donkey G6PD expression has recently been demonstrated by Cohen and Rattuzzi in the female mule (*Proc. US Nat. Acad. Sci.*, **68**, 544; 1971) and the two articles by Hamerton and Giannelli on pages 312 and 315 of this issue of *Nature* amplify these findings. With both the mule and the hinny, agreement was found between the frequency of cells in original fibroblast cultures with late replicating donkey or horse *X*-chromosome and the estimated frequency of cells in these cultures expressing donkey or horse G6PD, as determined by the yield of the two cell types in cloning experiments. Final proof of a definite relationship between late replication and genetic inactivity will be obtainable when late replication of the *X* is studied in horse and donkey G6PD clones.

Perhaps the most intriguing information provided by the present studies on horse–donkey hybrids is the discovery of extensive cell selection operating both *in vitro* and *in vivo*. In the *in vitro* studies this was best seen from the results of recloning mixed clones. If it is assumed that these mixed clones originated from two cells, one with the horse *X* active and one with the donkey *X* active, the proportion of sub-clones expressing the donkey G6PD is found to be significantly lower than that expected. Whereas this observation suggests powerful selective forces acting against cells with the donkey *X* active, it would be useful to subject this interpretation to test. This could be done by cloning cultures derived from artificial mixtures of the two cell types.

Hook and Brustman's article on page 349 provides striking evidence of organ differences in G6PD expression among a very large sample of female mules. Two organ types could be identified, one in which the horse G6PD predominates and one in which horse and donkey G6PD expression is not significantly different from that expected on a random basis. Because a predominance of donkey G6PD was never consistently found in any tissue studied, these data agree with Hamerton's in suggesting that selective forces operate against cells with the donkey *X* active, at least in some tissues and organs.

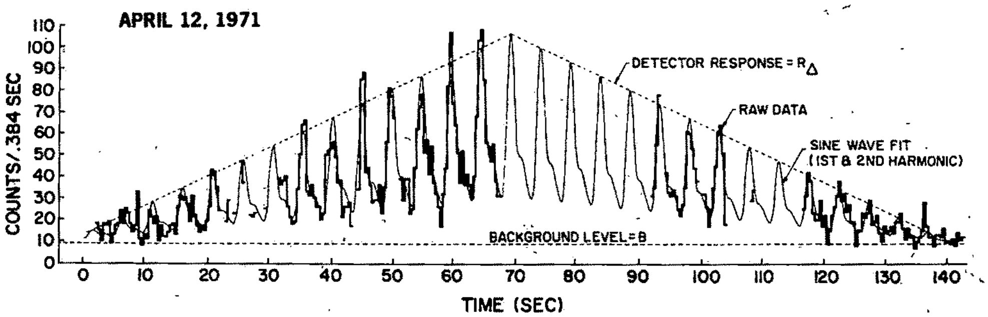
Earlier studies on the female mule had shown little agreement as to the frequency with which the horse and donkey *X*-chromosomes show late replication. In the light of the new evidence it seems most probable that this only reflected inter-animal variation. This could result either from the randomness with which one or other *X* is inactivated and/or from differences in the selection forces operating upon the two cell populations in different animals. In this context it will be interesting to see if selection operates against cells with a donkey *X* active even in animals which show a predominantly donkey G6PD expression. The new data do not contribute any evidence on the randomness of the *X* inactivation process in horse–donkey hybrids though they rule out the once real possibility that the paternally-derived *X* might be preferentially inactivated in the hybrid of each reciprocal cross.

New Class of Varying Stars

FOLLOWING the discovery of X-ray pulsations from Cygnus X-1, the data collected by the Explorer 42 X-ray satellite (Uhuru) have been intensively searched for evidence of any similar pulsations in other sources. To the surprise of most astronomers—and probably to their own surprise as well—R. Giacconi, H. Gursky, E. Kellog, E. Schreier and H. Tananbaum have now found that the source Centaurus

X-3 varies dramatically with a period of nearly 5 s, as shown in the figure. These variations are markedly different from the variations seen in pulsars, quite apart from the fact that in both Cyg X-1 and Cen X-2 there is no evidence of associated optical and radio pulsations (*Astrophys. J. Lett.*, **167**, L67; 1971).

The Cyg X-1 discovery itself caused quite a stir among astronomers and although this source has now been identified at radio frequencies (Braes and Miley, *Nature*, **232**, 246; 1971) it remains difficult to fit it into the accepted pulsar model. But the Cen X-3 discovery is even more remarkable, and although many people would be prepared to argue that the evidence for periodic variations in the X-ray flux from Cyg X-1 is so marginal that it could be discounted, it would be a brave man who ventured to suggest that the period seen in the flux from Cen X-3 is not a genuine effect (compare the figure here with that in *Nature Physical Science*, **231**, 91; 1971). The problem of the origin of these periodicities remains unsolved, but it is becoming increasingly clear that they cannot be interpreted in terms of the rotating neutron star model of pulsars.



X-ray variations of Centaurus X-3. Roughly 70 per cent of the power radiated at 2–6 keV is pulsed. From *Astrophys. J. Lett*, (**167**, L67; 1971).

In their latest report, Giacconi *et al.* discuss variations in the flux from Cen X-3 with time scales of days, minutes and seconds. Although the intensity of the source changed by a factor of 10 over January 11 and 12 of this year, the mean flux before and after this increase was remarkably constant. The almost sinusoidal rapid variation which is seen after this flaring has a period of 4.8713 s for the first 9,000 s after the flare, which changes over the next hour to a 4.8703 s period, this in turn lasting for roughly 28,000 s before changing, again over an hour, to a 4.8726 s period. This decrease by 1 ms followed by an increase by 2.3 ms poses serious problems in constructing models of the source. Furthermore, by April, the period of the variation had decreased by roughly 30 ms, that is, by 0.6 per cent.

In carrying out a search for evidence of any more rapid variation, the team have found only the "fundamental" 4.8 s period and a strong "first harmonic" at 2.4 s, using Fourier analysis of the January data. Any other rapid variations must occur with a time scale that is short compared with the 0.096 s integration time of the detector used. The presence of two harmonics in the variation, together with the sinusoidal shape of the curve which best fits the observed changes, also points to a pulsational origin, rather than one associated with rotation. Perhaps the pulsating white dwarf model of pulsars, discarded by theoreticians in favour of the rotating neutron star model, might be revived to explain this newly discovered phenomenon.

So Cen X-3, and in all probability Cyg X-1, cannot be fitted to the model of pulsars built up over the past three years. The sudden changes in period, the presence of overtones, and the simple fact that no optical or radio pulses are seen all point to the same conclusion. Do these sources form a new class of previously undetected objects? Or are they simply a previously unexpected manifestation of the pulsar phenomenon? In either case, there is a great deal of hard thinking ahead of the theoreticians. It may even be that Cen X-3 and Cyg X-1, as well as being different from pulsars, are entirely different sorts of object from each other. Indeed, the apparent differences between the spectra, Cyg X-1 following a power law and Cen X-3 seeming more like a blackbody, make it very likely that the sources have different origins.

Just as the development of optical astronomy earlier this century opened up unforeseen areas of research and led to the development of theories explaining the early and middle stages of stellar evolution, so high energy astronomy is now revealing equally unprecedented data, which may, when gathered into a coherent pattern, reveal the way in which stars move towards the end point of their evolution, producing short lived energetic phenomena such as pulsars and at least one or two types of regularly variable X-ray stars before they sink into obscurity as cold white dwarfs or neutron stars.

Confusion over Fossil Man

WHEN Leakey, Tobias and Napier redefined the genus *Homo* in 1964 they also described the type of the earliest known species of this genus, *Homo "habilis"*. The redefined genus as well as the new species have been the object of considerable discussion and dispute and the attribution of Olduvai Hominid 24 to *Homo habilis* by Leakey, Clarke and Leakey on page 308 of this issue of *Nature* will in no way lessen the controversy. The revised definition of the genus *Homo* included several cranial features that differed only slightly from, or overlapped with, those found in *Australopithecus*; indeed, many of the cranial criteria were so ambiguously flexible that perhaps only the odd gorilla would have been denied membership. It must be pointed out, however, that distinctions between genera are not subtle and overlapping features, but they reflect and represent major adaptations to a particular way of life; that is the "adaptive plateau" discussed by Sewall Wright, Ernst Mayr and others. It is difficult, therefore, for some palaeoanthropologists to accept as generically distinctive the differences in certain features in *Australopithecus africanus* and *Homo "habilis"* which are probably due only to normal variation within a single species. Moreover, the slow evolution of a single, widespread population of *Australopithecus* into *Homo* would seem more consistent with modern evolutionary theory than with the continued existence of several generically and specifically distinct groups of hominids.

Criticisms of theory aside, it is interesting and surprising to find that the new *Homo "habilis"* from Olduvai does not fulfil all the generic criteria outlined in the 1964 revision. The revision calls for a minimum cranial capacity of "about 600 cm^3". Although some gorillas have more than 600 cm^3, Olduvai Hominid 24 has only 560 cm^3. This is admittedly a preliminary estimate because there is "still some evidence of distortion in the reconstruction" and two inevitable questions arise: if cranial capacity cannot be accurately determined does this not undermine the validity of many of the cranial measurements? And does it not also undermine the validity of the conclusions that are drawn, at least in part, from those measurements?

One taxonomic criterion included in the 1964 revision was not phrased in equivocal terms: a member of the genus *Homo* will not have the concave or "dished" face characteristic of all known australopithecines. The dished face is a composite feature of considerable evolutionary significance and its absence in later hominines represents a diminution of the teeth and jaws, with reduced prognathism in the lower part of the face and emergence of the nose. The profile line drawing (Fig. 3 on page 310) clearly demonstrates the dished face of Olduvai Hominid 24 and serves to emphasize its overall similarity with the undoubted australopithecine from South Africa.

Olduvai Hominid 24 has been nicknamed "Twiggy" because its flattened shape before restoration resembled that notably unendowed figure. A badly crushed and distorted skull nearly two million years old presents some problems to those restoring it; it presents even more problems to those who try to decide, finally, what it is. On the basis of the evidence presented by Dr Leakey it is very difficult to agree that this specimen is "clearly *Homo*". Indeed it would seem to be excluded from that group on the basis of his own criteria are outlined in his 1964 article.

TRANSFORMATION

Responses to Cyclic AMP

from our Cell Biology Correspondent

EARLIER this year I drew attention in this column to the work of Puck and his associates and Pastan's group who respectively showed that dibutyryl adenosine cyclic 3′,5′ monophosphate causes Chinese hamster ovary cells growing in culture to assume reversibly a fibroblastic morphology, and causes the phenotypic reversion of transformed mouse fibroblasts. More recently *Nature's* Cell Physiology Correspondent (*Nature New Biology*, **232**, 35; 1971) commented upon the experiments of Sheppard, who has shown that doses of this substituted cyclic AMP not only restore the growth control and susceptibility to contact inhibition of populations of 3T6 cells and 3T3 cells transformed by polyoma virus but also reduce the susceptibility of these cells to agglutination by wheat germ agglutinin.

Myoglobin Sequence Completed

THE torrent of articles concerned, on the one hand, with the structure and function of haemoglobins and on the other with the characterization of variant haemoglobins, shows no sign of abating. A welcome addition, however, is the appearance, in next Wednesday's *Nature New Biology*, of three articles on the sequence of human myoglobin, the choice of an allosteric model for the haemoglobin-oxygen system, and the relation between structure and properties of the Japanese human haemoglobin variant Hb-Hiroshima.

Herra and Lehmann have repeated some parts of Hill's sequence studies on human myoglobin and disagree with him on only three points. They have also completed the sequence which largely agrees with that proposed from considerations of amino-acid composition and homology with the known sequence of sperm whale myoglobin. Their sequence allows the differences between seven myoglobins to be delineated and will no doubt stimulate discussion on the homology and evolution of mammalian myoglobins. The unique feature of human myoglobin is a cysteine residue at position 110 (G11), which it has in common with the α-chain of human haemoglobin. Apart from this feature, human myoglobin resembles the human α-chain to no greater extent than the β-chain, having thirty-seven identical residues with each. Of these several are discovered among the haem contacts of the α and β-chains.

The complete human myoglobin sequence will be of great value in determining the structural differences of the four known human skeletal myoglobin electrophoretic variants; the possible existence of neutral mutations can also be investigated. Herra and Lehmann report no differences in the fingerprints of human skeletal and heart myoglobin and the skeletal myoglobin of a case of Duchenne's muscular dystrophy. Further work on human myoglobin variants, which has in the past been an area of some confusion, will be awaited with interest.

Connoisseurs of theories of allosteric systems will no doubt appreciate a re-examination by Minton in next Wednesday's *Nature New Biology* of a recent treatment by Edelstein (*Nature*, **230**, 224; 1971) of the allosteric model for haemoglobin. Edelstein had concluded that the sequential model of Koshland, Nemethy and Filmer describes the oxygen binding curves of several species of human haemoglobin less well than does the two-state model of Monod, Wyman and Changeux. Minton points out that a tacit assumption in Edelstein's analysis is likely to be invalid, in which case it cannot be shown that any one of the two models is more appropriate to describe the haemoglobin-oxygen system.

In another article, Perutz and Shibata and their co-workers have re-investigated the Japanese haemoglobin variant Hb-Hiroshima, in which the magnitude of the Bohr effect is halved, the oxygen affinity at physiological *p*H is increased three times and the haem-haem interaction is somewhat reduced. This variant was thought to have the substitution β143 (histidine→aspartic acid), but the normal effect of 2,3-DPG on the oxygen affinity of Hb-Hiroshima was inconsistent with the proposed role of this residue in the binding of 2,3-DPG by normal adult haemoglobin.

Perutz and his colleagues have now been able to show, both by X-ray crystallography of deoxy Hb-Hiroshima and by chemical methods, that the replacement is in position β146. The physiological properties of Hb-Hiroshima can now be accounted for without difficulty. The result also confirms the earlier suggestion that half the alkaline Bohr effect is due to the salt bridge between the imidazole side chain of β146 (His) and the γ-carboxyl group of β94 (Asp). The reduced haem-haem interaction in Hb-Hiroshima is also related to the absence of a histidine residue at β146, which affects both the tertiary structure of the β-chains and the quaternary structure of the entire molecule.

In the latest issue of the *Proceedings of the US National Academy of Sciences* (**68**, 1648 ; 1971), Hsie, Jones and Puck describe their latest observations of Chinese hamster ovary cells exposed to dibutyryl cyclic AMP alone or in combination with a variety of steroid and other hormones. The change in morphology and pattern of growth of these cells on exposure to this substituted cyclic AMP is accompanied by a strict susceptibility to contact inhibition of growth and a decreased susceptibility to agglutination by wheat germ agglutinin. Moreover, in the presence of dibutyryl cyclic AMP Chinese hamster ovary cells fail to round up when exposed to concanavalin A or antibody lacking complement. The synthesis of collagen as judged by the intracellular concentration of hydroxyproline, which is of course a characteristic property of fibroblasts the expression of which may be modulated by virus transformation, is, however, increased six to ten times when these ovary cells are exposed to the drug.

Puck and his colleagues have also tested a wide range of male and female steroid sex hormones to discover whether the synergistic effect of testosterone on the morphological conversion induced by dibutyryl cyclic AMP is highly specific or common to many if not all steroids. They found that the male steroid hormones and some prostaglandins all have this property but the steroid oestrogens do not. Apparently the group have isolated mutant cells which have a fibroblastic morphology even in the absence of cyclic AMP; they believe that these cells carry single gene mutations and their analysis—an exciting prospect—should turn attention to the genetic control of morphological and biochemical transformation induced by this unique nucleotide.

It would be wrong, however, to run away with the idea that the multiplication of all cells is inhibited, or at least brought under strict contact inhibitory control, by cyclic AMP. For MacManus, Whitfield and Youdale, in an interesting article published earlier this year (*J. Cell Physiol.*, **77**, 103 ; 1971), reported that when rat thymic lymphocytes are exposed to epinephrine (adrenaline) the intracellular concentration of cyclic AMP and the activity of adenyl cyclase are both increased. And in due season these changes are followed by the induction of DNA synthesis and mitosis.

In other words, although cyclic AMP may suppress the unregulated multiplication of transformed fibroblasts and impose contact inhibition of Chinese hamster ovary cells, it, and its inducers, are mitogenic for suspensions of rat thymocytes, causing these cells to proliferate.

PHOTOCHEMISTRY

Dark Photobiology?

from our Biological Chemistry Correspondent

THE susceptibility of the nucleic acids to photochemical change on ultraviolet irradiation has been thoroughly explored. The mutagenic and lethal effects which follow such chemical modification of the bases are, for the most part, relieved by enzyme repair systems. Even in those unfortunate individuals where such repair is defective, it has been generally assumed that the resulting photochemical damage would be solely restricted to those cells on the surface of the organism which are exposed to ultraviolet irradiation.

This restriction is now questioned by the elegant demonstration that pyrimidine dimers can be formed as a result of the generation of electronically excited molecules without light. Lamola selected trimethyl-1,2-dioxetane for this purpose because it is known to thermally decompose into excited state acetone and acetaldehyde and such carbonyl compounds have triplet-state energies closely matched to those of thymine and cytosine.

As expected, when the dioxetane was decomposed at 70° in the dark in the presence of *Escherichia coli* DNA, Lamola was able to isolate pyrimidine "photodimers" from both thymine and cytosine residues (*Biochem, Biophys. Res. Commun.*, **43**, 893; 1971). Although he estimates the efficiency of this process to be not much more than 1 per cent of the photosensitized reaction, the hunt must be on for other electronically excited promoters both to raise the level of dimerization and to provide a biological model.

There is no speculation in the photochemical modification of those tRNAs which contain 4-thiouracil because this base is excited by medium-wavelength ultraviolet light at 334 nm. Favre, Yaniv and their colleagues (*J. Mol. Biol.*, **58**, 367 and 381 ; 1971) now provide some of the facts about the results of such irradiation. A 4-thiouracil at position-8 becomes covalently linked to a cytosine at position-13 in $\mathrm{tRNA}_{\mathrm{I}}^{\mathrm{Val}}$ and in five other tRNAs which all have those residues in common. Thus it seems likely that these six tRNAs have similar structures.

The nature of the linkage is not clear, though it is distinct from that in known photodimers and survives borohydride reduction of the tRNA in a modified form which provides a new fluorescent chromophore in the molecule. This fluorescence can be used to probe changes in the tertiary structure of the modified tRNAs and reveals that they have experienced very little change in segments of the tRNA other than that containing residues 8 and 13.

Contractile Microfilaments

A SURPRISING result has emerged from recent structural and chemical studies of motile processes in cells. The proteins actin and probably myosin as well, which were formerly thought to be present only in muscle cells, are in fact widely distributed in a variety of cell types. Microfilaments, structures 40–60 Å in diameter, which have been shown in some cases to be composed of an actin-like protein, appear to be involved in protoplasmic streaming, cytokinesis, formation of a ruffled membrane, nerve outgrowth and various morphological movements. In next Wednesday's *Nature New Biology*, Allison, Davies and de Petris describe the participation of microfilaments in phagocytosis and pinocytosis by mouse peritoneal macrophages.

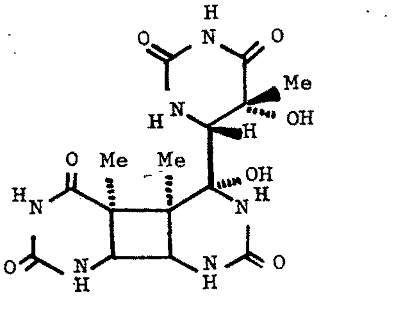
Two techniques have been responsible for recent advances—an apparently specific test for the identification of actin-like microfilaments and a specific inhibitor of microfilament function. Heavy meromyosin forms a complex with actin in which the asymmetric myosin molecule is at 45° with the actin filament leading to a characteristic "chevron" appearance. Glycerination, which allows entry of the myosin, enables microfilaments to be identified within the cell. It was first shown by S. B. Carter (*Nature*, **213**, 261 ; 1967) that the drug cytochalasin B breaks down microfilaments, and various functions of microfilament have been blocked by this compound (N. K. Wassells *et al.*, *Science*, **171**, 135 ; 1971).

Allison and his collaborators show that macrophages contain bundles of filaments in the peripheral cytoplasm which bind heavy meromyosin. Cytochalasin reversibly blocks cell movement, ruffled membrane formation and pinocytosis in these cells. Phagocytosis of bacteria is also blocked even though the bacteria still attach to the plasma membrane. Treatment with colchicine, a specific inhibitor of microtubule dependent processes, does not effect pinocytosis.

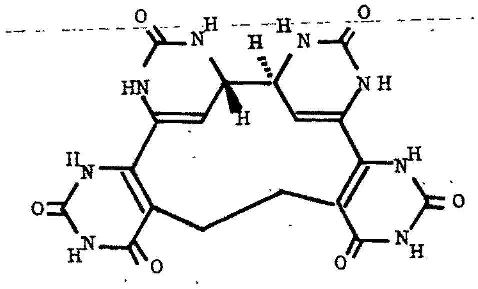
The ability to distinguish between the functions of microtubules and microfilaments by specific drugs and the isolation of both proteins have opened the way for an understanding of the functioning of fibrous proteins in intracellular and morphogenetic movements.

The thiouracil-cytosine linkage does, however, have small effects on the biological activity of the tRNA which is shown in a reduced affinity for the synthetase and a slower rate of incorporation of valine from the charged tRNA into polypeptides during protein synthesis.

The photoproducts so far isolated from DNA never contain more than two pyrimidines linked together. Wang, however, has isolated and characterized trimers and tetramers from irradiation of pyrimidines in ice matrices and in water (*J. Amer. Chem. Soc.*, **93**, 2554 and 2768; 1971) which could prove to have biological counterparts. The trimer in particular has the interesting property of reverting either to thymine and thymine dimer or to thymine and a thymine-adduct.



I



II

The structure (I) of the trimer and that of the tetramer (II), produced on irradiation of a thymine-uracil photoproduct, have been elucidated by Flippen and Karle (*J. Amer. Chem. Soc.*, **93**, 2556 and 2762; 1971) by X-ray diffraction.

ANTIBODIES

Garnering γGlobulin

from our Molecular Biology Correspondent

A 6 Å electron density map of an immunoglobulin has now been achieved by Davies and his colleagues (Sarma *et al.*, *J. Biol. Chem.*, **246**, 3753; 1971) and is in gratifying accord with what has been deduced about the shape of the molecule by electron microscopy and other methods. In the crystal the molecules have a dyad symmetry axis, and the electron density distribution is interpretable in terms of three globular elements, joined together so as to form a T-shape, the stem consisting of the so-called Fc portion which is attached by means of a rather narrow hinge to the two Fab components. The hinge gives access to proteolytic enzymes, which cleave at this point, and is surmised from a variety of lines of evidence to be flexible when the molecule is in solution. The size and shape of the Fc unit are in good agreement with data derived from a study of the crystals of this fragment alone from Poljak's laboratory.

In a companion article, Lebaw and Davies (*ibid.*, 3760) show electron micrographs of the immunoglobulin crystal. They utilize the magic of optical integration—whereby multiple prints of the micrographs are made, advancing the photographic paper each time under the enlarger by a distance corresponding to the periodicity. The picture of a well-dug field then gradually resolves itself into a sharply-defined pattern, in which the repeating unit stands out as a T or Y shape, somewhat smaller than the hydrated molecules observed by X-ray diffraction in the unfixed crystal, but exactly like the isolated molecules observed in the electron microscope by Valentine and Green some years ago.

These γG-immunoglobulin molecules consist of two heavy and two light chains, joined together by disulphide bonds, but other forms exist with a higher level of complexity. Thus electron microscopy has shown macroglobulin (immunoglobulin M) to consist of a cyclic pentamer of γG-like (7S) subunits. The units are joined by disulphide bonds between their Fc regions. The determination of the sequence of events in the assembly, first of the four-chain structure, then of the pentameric form, has been one of the recent triumphs of the field, and some details of the mechanism are described in the latest article by Askonas and Parkhouse (*Biochem. J.*, **123**, 629; 1971). They showed previously that inside the tumour cells, in which the macroglobulin is made, only the 7S subunits are present. By the time the newly synthesized protein is secreted assembly to the complete pentamers has occurred. When the subunits from lysed cells are allowed to stand in air, no pentamers

---

The Truth about Juan de Fuca

THE appealing simplicity of seafloor-spreading is probably an illusion on two counts. First, it would be surprising if a conceptual model so simple were to be rigorously applicable to a real Earth which is manifestly so complex, although the seafloor spreading model in its most basic form has done much to unify the Earth sciences. Current ideas on spreading will in the course of time no doubt come to be seen as a first approximation rather than as a detailed hypothesis for the behaviour of the Earth. But second, and perhaps more obviously, even if the seafloor is being, and has been, formed in a simple way, the final picture is likely to be quite complex. For notwithstanding the comparative youth of the oceans, changes may have taken place in the structure of the ocean floor since spreading began. Indeed, considering the state of activity in the oceanic crust it would be surprising if they had not.

As Peter and DeWald show in next Monday's *Nature Physical Science*, a good example of the latter type of complexity is the ocean floor off the north-west coast of the United States. Here the Juan de Fuca, Gorda and Explorer Ridges, each of which is offset from the others and each of which trends in a north-easterly direction, were clearly formed as a single rift but have since been subject to numerous fractures. The first job is thus to try to construct an authentic map of the anomalies and faults in the region; and this is what Peter and DeWald have done, partly with the help of data previously published and partly with thirteen new east–west magnetic traverses carried out off the coasts of Washington and Oregon.

Examination of the pattern of magnetic offsets clearly shows the existence of a previously undiscovered fracture zone separating the mountainous ridge topography from the Tufts Abyssal Plain. This Peter and DeWald have termed, appropriately, the Juan de Fuca Fracture Zone. But, more importantly, the discovery of the new fracture taken in conjunction with the complete anomaly map has enabled Peter and DeWald to end the speculation about why the original ridge broke up and why its component parts now trend north-east. The fact is that some of the anomalies west of the Juan de Fuca Ridge are missing and obviously disappear along the newly discovered fracture zone which coincides with a 550-metre change in seafloor relief. This must indicate deformation involving rotation, strike-slip faulting and the over thrusting of small crustal plates; and according to Peter and DeWald the most likely cause is compression in the roughly north-east–south-west direction. What is now quite clear is that the ridge trends in this region cannot be attributable to anything as gradual as a slow realignment produced by a change in the direction of seafloor spreading.

are formed. The finished pentamers are easily reduced, and electrophoretic analysis shows that 7S monomers are first formed—as well, apparently, as some oligomeric intermediates. At higher concentrations of reducing agent the intra-subunit disulphide bonds begin to break, and HL pairs (one heavy with one light chain) appear, showing that the internal H–H disulphide bonds are next in order of lability. Finally, the remaining (H–L) links break and single heavy and light chains are produced. The 7S monomers, allowed to oxidize in air, regenerated the inter-subunit disulphide bonds and the pentamers were once more formed in high yield. When the free thiols were blocked with iodoacetamide no pentamers appeared.

Evidently then, the freshly synthesized, intracellular, subunits, which resist all attempts to make them polymerize, differ in the reactivity of their thiols, and Askonas and Parkhouse conjectured that these might be chemically protected. An obvious mechanism for easily reversible modification would be the formation of a mixed disulphide with a thiol present in the cell. Their surmise proved correct: treatment of the molecule with a reducing agent in low concentration converted it to a form that readily generated pentamers on standing. Exposure to the alkylating agent iodoacetamide before this reduction step had no detrimental effect, whereas alkylation after the reduction caused total inhibition of polymerization. The nature of the blocking group is unknown; cysteine or glutathione are obvious candidates, though an especially attractive alternative would be an intra-chain disulphide bond. Such a situation would be reminiscent of the formation of streptococcal protease from its zymogen by reduction of a disulphide bond. One must suppose that the liberation of thiols and polymerization occur during the passage of the immunoglobulin monomers through the membrane, where, it will be recalled, the disulphide-exchange enzyme is known to reside.

The earlier stage of synthesis—the association of light and heavy chains to give 7S subunits—has been studied by Parkhouse (*ibid.*, 635). The most stable disulphide bonds—those between light and heavy chains—are formed first, and the two HL fragments then associate. Pulse-labelling studies show that the light chains are present in a sizable pool.

Other disulphide-linked oligomers (IgA) are secreted by tumour cells of a different kind, and Parkhouse (*FEBS Lett.*, **16**, 71 ; 1971) has shown that here too only the 7S form is present in the cell. Oligomers up to the tetramer are formed; the disposition of the linking groups in this case evidently does not favour pentameric cyclization. In this species, moreover, the association between heavy and light chains is non-covalent only.

HIGH ENERGY PHYSICS

The Elusive Quark

from a Correspondent

RECENT experimental studies at Livermore and Berkeley of more than 100,000 cosmic ray tracks from extensive air showers have failed to reveal any tracks made by fractionally charged particles and so another search for quarks has proved fruitless (A. F. Clark *et al.*, *Phys. Rev. Lett.*, **27**, 51 ; 1971).

The hunt for quarks has been going on since their existence was independently proposed by Murray Gell-Mann and George Zweig in 1964. They have been looked for since then with particle accelerators, in cosmic radiation, and in investigations of macroscopic material, for example seawater: most of these searches rely on the fact that the quarks should possess nonintegral electric charges of one-third, or two-thirds of that of the electron, and should therefore yield tracks in particle detectors with substantially lower ionizations than conventionally charged particles.

Although no substantiated evidence for the quark has been revealed by these investigations, there have been a few false hopes. In 1969, an Australian group, led by C. B. A. McCusker of the Cornell-Sydney University Astronomy Centre, claimed that certain anomalies, observed in cloud chamber studies of cosmic ray ionizations, were most likely to have been caused by quarks of charge $\frac{2}{3}e$ (*Phys. Rev. Lett.*, **23**, 658 ; 1969).

Five candidates for such quark events were reported from a total of some 6,000 cloud chamber photographs. This result was greeted with some scepticism by the physics community and was soon under severe attack: an article by R. K. Adair of Yale University and H. Kasha of Brookhaven (*Phys. Rev. Lett.*, **23**, 1355 ; 1970) indicated that the anomalously low ionizations reported by McCusker *et al.* were probably due to low energy electrons and muons associated with the air showers. A more recent report of a quark sighting by a group from Ohio State University, and based on a cosmic ray bubble chamber photograph, has also received very little support (W. T. Chu *et al.*, *Phys. Rev. Lett.*, **24**, 917 ; 1970).

Escaping Atmospheres

A CONTINUAL battle rages between the high-speed molecules trying to fly off from the Earth's atmosphere and the gravitational attraction trying to restrain them. For some planets, like the Earth and Venus, gravity has triumphed over levity up to now, but for the Moon, and probably Mercury, most of the escaping molecules have eluded their gravitational jailers; on Mars the issue is still in doubt, and a thin atmosphere persists, rather precariously.

The escape of molecules from the outer atmospheres of planets is determined chiefly by the temperature prevailing in the region, usually called the exosphere, where the mean free path of molecules is greater than the scale height—the height in which pressure and density decline by a factor of 2.8. In an article in next Monday's *Nature Physical Science*, S. J. Bauer describes a method for estimating this temperature in planets like Venus and Mars and hence the atmospheric escape rate.

If the molecules in the exosphere have thermal velocities higher than the escape velocity from the planet, the molecules travelling upwards are not very likely to suffer further collision, and will usually escape. The escape velocity for the Earth is between 10 and 11 km s^{-1} and this is the thermal velocity corresponding to a temperature of about 4,000 K for hydrogen atoms (or 16,000 K for helium atoms). The actual temperatures at the base of the Earth's exosphere, at a height of about 500 km, are determined largely by the heating at lower heights (100 to 200 km), where solar extreme ultraviolet radiation is absorbed. On Earth it so happens that the solar radiation does not usually produce exospheric temperatures greater than 2,000 K, and even these temperatures are only maintained during a high maximum of solar activity, like that in 1957 and 1958. So, although there is no guarantee that the Sun will continue to be so cooperative, the present loss of hydrogen from the Earth's temperature is not too serious. There is always some loss, however, because the high-velocity tail of the Maxwellian distribution of thermal velocities can make its escape unchecked.

For the Earth, Bauer has calculated that the exospheric temperature at a strong solar maximum (2,000 K) is about 2.5 times that at solar minimum (800 K). For Venus and Mars, he suggests that the corresponding factor is about 1.7, and concludes that Earth and Venus have exospheres which, although subject to some loss, are stable even at solar maximum, whereas the atmosphere of Mars is stable only near solar minimum and suffers large losses at solar maximum.

The experimental technique used by Clark *et al.* was similar to that used by McCusker *et al.* and was based on cloud chambers triggered by coincidence counters. Artificially produced low-droplet count tracks were used to determine the detection efficiency for quark-like tracks, and from this the US group claim that their scanning team would have picked up four of the original five quark candidates found by the Sydney team. They concluded that no quarks had been observed, so that, for the present at least, quarks must remain essentially a convenient mathematical abstraction.

The story, however, is by no means over. On the theoretical side, the now fashionable parton picture of particle structure has stimulated renewed interest in quarks. Parton is the name given by theorist Richard Feynman of the California Institute of Technology to the unknown constituents of the nucleons and attempts have been made to equate the parton and the quark. On the experimental side, quark searches have been proposed for the giant new accelerator at Batavia, Illinois, and without a doubt the physicists working with CERN's new intersecting proton storage rings will maintain a sharp vigil for anomalously ionizing radiation. Meanwhile, most high energy physicists are still keeping an open mind on quarks, and awaiting further developments.

NARCOTICS

Antagonist Activities

from a Correspondent

FUNDAMENTAL to the symposium of the British Pharmacological Society on agonist and antagonist activities of narcotic analgesic drugs, held at the University of Aberdeen on July 12 and 13, was the concept that nearly all drugs of the group discussed possess both agonist and antagonist properties. This concept originated from the findings of L. Lasagna and H. K. Beecher in 1954 that the morphine antagonist nalorphine itself has analgesic properties, and of J. E. Villarreal about ten years later that some powerful analgesics of this group have enough antagonist activity to precipitate abstinence effects in morphine-dependent monkeys. The concept was quantified by H. W. Kosterlitz and his co-workers, who measured in the isolated ileum of the guinea-pig the opposed activities of drugs of this group, believed to correspond with their agonist and antagonist actions in the central nervous system. Using this simple model, these workers at the University of Aberdeen were able to place these drugs in descending order of the ratio of the agonist to antagonist activities that each possessed, making a series beginning with the powerful analgesics heroin and morphine and ending with the seemingly "pure" antagonist naloxone. At the symposium, the validity of this procedure was supported by measurements of the antinociceptive and morphine-antagonist potencies of six drugs in this series in the rat and mouse by Drs H. O. J. Collier and C. Schneider (Miles Laboratories Limited, Stoke Poges). These measurements placed the drugs in an essentially similar order to that obtained with the guinea-pig ileum.

These experiments, both *in vitro* and *in vivo*, showed that the analgesic pentazocine possesses appreciable antagonist activity, placing it at a point some distance down the series from morphine in the direction of naloxone. That pentazocine is freer of addictive liability than is morphine or heroin supports the idea that this liability diminishes as the antagonist activity of an analgesic increases. A paper by Dr G. F. Blane (Reckitt and Colman, Hull) and other contributions indicated that the advent of pentazocine has changed the search for new drugs of this group by lessening the acceptability of compounds with a high agonist to antagonist ratio and hence high addictive liability.

With the increase in drug addiction, much of the work reported at the symposium was slanted towards problems of dependence on opiates. The directions explored owed something to suggestions about the mechanism of drug dependence advanced during the 1960s by A. and D. B. Goldstein, W. D. M. Paton, H. O. J. Collier and others. Thus, Drs E. L. Way (University of California, San Francisco) and B. M. Cox (Chelsea College of Science and Technology, London) have found that drugs blocking protein synthesis inhibit the development of dependence as well as tolerance towards morphine. Again, Drs T. C. Muir and D. Pollock (University of Glasgow)

Agglutinins and the Cell Surface

DURING the past eighteen months plant agglutinins, or lectins as they are sometimes called, have become a major topic of conversation in many cancer research laboratories; for, as Burger and his colleagues at Princeton and Sach's group at Rehovot have shown, these substances preferentially agglutinate certain spontaneously and chemically transformed cells and some cells transformed by DNA tumour viruses. Moreover, a considerable collection of circumstantial evidence has been accumulated which suggests that the changes in the cell surface which can be monitored by measuring susceptibility to agglutination are intimately and perhaps causally connected with the regulation of cell division (see, for example, *Nature*, **228**, 502; and **228**, 512; 1970).

It has generally been assumed that, because transformed cells are more readily agglutinated by lectins such as concanavalin A and wheat germ agglutinin, transformation must result in the exposure of receptor sites which bind these molecules. In other words, the simple idea was that the transformed cell has more of these binding sites exposed on its surface than does the untransformed cell and that this surface change was somehow involved in the unregulated growth of transformed cells. In next Wednesday's *Nature New Biology*, however, the research groups of Ozanne and Sambrook and Cline and Livingston put a cat in this particular dove-cote.

Using either concanavalin A or wheat germ agglutinin labelled with ^{125}I or concanavalin A labelled with ^{3}H, they have shown that although BHK hamster cells and mouse 3T3 cells transformed respectively by polyoma virus and SV40 are more readily agglutinated than the corresponding untransformed cells, the untransformed and transformed cells bind, on a per milligram of protein basis, about the same amounts of both concanavalin A and wheat germ agglutinin.

In other words, there is no correlation between the amount of lectin a cell can bind and its susceptibility to agglutination by that lectin. The increased susceptibility to agglutination of transformed cells does not result from the exposure of more lectin-binding sites at the cell surface. The most convincing and elegant proof of these statements is provided by Ozanne and Sambrook who have measured the binding capacity and agglutinability of hamster BHK cells transformed by the temperature sensitive mutant of polyoma virus *ts*3. Growing at 32° C these cells are agglutinated by low concentrations of concanavalin A or wheat germ agglutinin but when they are shifted to 38.5° C much larger amounts of the lectins are needed for agglutination. The amount of lectin bound, however, is the same at both temperatures.

Clearly, increased susceptibility to agglutination reflects surface changes more subtle than an increase in the number of lectin-binding sites and as Ozanne and Sambrook say "it seems difficult to postulate a general mechanism of growth control based solely on the number of exposed lectin binding sites".

reported that, in the rat, the response of smooth muscles to adrenergic or cholinergic stimulation greatly increased after the withdrawal of chronic treatment with morphine—reaching a peak three days later.

In another direction, the mechanisms of dependence suggested some years ago require an interaction of morphine with a humoral mediator involved in the activity of neurones in the brain. In this direction, some setbacks and some encouraging findings were recorded. On the one hand, the evidence adduced by Drs A. Goldstein (Stanford University) and I. Marshall (St Mary's Hospital Medical School, London) was against the proposition, stoutly defended by Dr Way, that a change in the level or turnover of brain 5-hydroxytryptamine is important in morphine dependence in the mouse. On the other hand, C. B. Smith and J. E. Villarreal (University of Michigan, Ann Arbor) reported that continued treatment with morphine and other addictive opiates increases the incorporation of ^{14}C-tyrosine into the noradrenaline and dopamine of the brain of the mouse. The increased turnover of brain catecholamines can not be induced by strong antagonists of morphine and is blocked by naloxone; in the author's opinion it is correlated with addictive liability in this group of drugs.

BACTERIOLOGY

More Pollution

from a Correspondent

THE summer conference of the Society for Applied Bacteriology was held at the University of Liverpool from July 13 to 15 and took the form of a symposium on the microbial aspects of pollution. The contributions and subsequent discussions interpreted the title in the broadest possible terms so that well discussed topics, such as the pollution of the aquatic environment, and lesser known forms of pollution, such as the disposal of infected laboratory materials, were included. Few new data were presented, but they illustrated the importance of microbiological processes in the armoury for combating today's pollution problems.

Dr A. L. Downing (Water Pollution Research Laboratory, Stevenage) warned microbiologists not to get too excited at the prospect of an increased number of jobs for their profession in this expanding field because the introduction of new and more stringent existing standards for effluent quality could well result in non-biological methods becoming increasingly more important.

Problems pertaining to the eutrophication of surface waters were covered in detail by four speakers. Professor P. L. McCarty and Dr R. T. Haug (Stanford University, California) discussed the various methods available for the removal of nitrogen from sewage effluents by the microbiological processes of nitrification and denitrification and presented evidence for supporting the use of aerobic and anaerobic upward-flow submerged filters. Dr N. P. Burman (Metropolitan Water Board, London) pointed out, however, that the removal of nitrogen and phosphorus from sewage effluents was not always the answer to eutrophication problems, and gave the example of the Thames valley reservoirs where eutrophic conditions were inevitable because sufficient quantities of these elements were available from sources other than sewage.

Aerobic and anaerobic biological treatment of sewage and sewage sludges was discussed from both the microbiological and applied points of view and it was particularly encouraging to hear that the lead given by the detergents industry which changed from the production of biologically "hard" to "soft" materials is seriously being considered by industries producing other widely used materials. First, Dr H. O. W. Eggins (University of Aston) spoke on the possibilities of the plastics industry producing materials with parts in the chemical chain susceptible to microbial attack which would cause depolymerization and allow the subsequent attack of the smaller molecules by other microbes. Second, Dr S. L. J. Wright (Bath University of Technology) stated that a particularly attractive idea concerning the degradation of herbicides was the possibility of spraying the treated soil with an appropriate active microbial culture after an optimum time; preliminary experiments had already met with success. Third, Dr R. E. Cripps (Shell Research Ltd, Sittingbourne) spoke of his work on the relation between the chemical structure of pesticides and the possibilities of their degradation by microbial populations.

Chromosome Replication in Two Directions

FOR the double stranded and covalently closed circular DNA molecule which constitutes the chromosome of *Escherichia coli* to replicate in a semiconservative fashion the two parental strands of DNA must separate. There is, of course, evidence indicating that this separation is achieved by breaking phosphodiester bonds of the backbone of one of the two strands such that the nicked strand can be unwound from the circular strand. (Whether a single nick suffices or the chromosome is repeatedly nicked during replication is in the long run immaterial, for the net result is the same.) Moreover, genetic experiments have shown that replication begins and proceeds sequentially from a fixed point on the chromosome, the origin of replication. In theory at least replication might proceed in one or in both directions from this origin and until now it has generally been assumed that replication is unidirectional, proceeding 360° from the origin back to it. In next Wednesday's *Nature New Biology*, however, Masters and Broda challenge this notion; their experiments lead to the conclusion that replication occurs in both directions from the origin.

Masters and Broda have, in essence, measured the frequency of occurence of particular genetic markers situated at either side of the origin of replication in cultures of cells growing at different rates. They used the generalized transducing phage P1 which picks up *E. coli* genes at particular frequencies dependent on the number of copies of the genes present in the cell and the ease with which they can be integrated into the phage genome.

Ratios of the frequency of particular genetic markers measured in this way fall on a two directional gradient when plotted against the markers' genetic map positions. Moreover, a series of elegant transduction experiments with various male and female strains of *E. coli* indicate that the relative frequency of transduction of a particular marker depends on the position of that marker in the chromosome.

In dividing cells it seems that there are more copies of markers immediately adjacent to both sides of the origin of replication than there are copies of genes distal from the origin and genes close to the origin are more often transduced than genes distal from it. Both these findings indicate that replication proceeds in both directions from a fixed origin. Furthermore, assuming that the current genetic map accurately represents the length of DNA between markers, it seems that the rate of replication in the two directions is not the same. The terminus of replication is not 180° from the origin and replication in a clockwise direction about the chromosome seems to be faster than replication in the counterclockwise direction. In other words, Masters and Broda claim that replication of the *E. coli* chromosome is bidirectional but asymmetric and, as they note, Caro and his colleagues have reached the same conclusion from quite different experiments.

Why Hydrology?

JOHN C. RODDA
Institute of Hydrology, Wallingford, Berkshire

The International Hydrological Decade is now more than six years old and decisions about future international cooperation must soon be taken if the impetus given to hydrology during this period is not to be lost.

WHY hydrology? What is the point of studying the circulation and distribution of the world's freshwaters? Why bother with this science concerned with the rain and what happens to it when, in Britain at least, there always seems to be so much of it? Perhaps these questions and others like them were relevant twenty or thirty years ago, but not today; not when the consumption of water in the United Kingdom is rising at such a rate that demand will probably double by the end of the century and when the dry weather flow in a large number of rivers consists almost entirely of treated effluent from sewage works. In fact the Central Advisory Water Committee has recently made it clear[1] that re-use of this treated water will become increasingly important for supply purposes in the future.

Then at the other extreme, there are the floods that affect different parts of the country each year and can cause damage costing several million pounds annually. Fortunately loss of life occurs less frequently, but there can always be other disasters on the scale of that at Lynmouth in 1952. In fact there is some indication that the incidence of heavy rain is increasing; for example, on July 10, 1968, parts of Somerset and Gloucestershire recorded more than 130 mm of rain in 18 h, and in September of the same year parts of Kent, Surrey and Sussex experienced rainfalls of similar intensities. Even these rates of rainfall are, however, low on a world scale that reaches 1,500 mm a day for some Indian Ocean islands. One consequence of these relatively low intensities is that soil erosion is not the problem in Britain that it is, for example, in New Zealand. Nevertheless rivers draining the moorlands and mountains transport considerable amounts of sediment during flood, particularly when hill pastures have been ploughed recently. This also applies to almost any part of the country where building and construction are in progress on a large scale.

Facing the Hazards

Flood, erosion, drought and pollution are high on the list of hazards confronting man and they are also the chief problems facing the hydrologist. Can floods be forecast and drought severity predicted? Can the controls of the quality of the water flowing in a river be understood satisfactorily? These are questions that involve hydrologists the world over, but the fact that vast sums of money are spent in water supply schemes, flood alleviation works and sewage treatment plants, in order to mitigate the effects of these hydrological hazards, is usually taken for granted. In the same way, minimal attention is paid to the continuing research programmes into water problems which provide a basis for the design of these schemes and works. The aims and objects of the International Hydrological Decade (IHD), for example, are relatively little known. Other worldwide scientific programmes such as the International Geophysical Year (IGY) and International Biological Programme (IBP) have received far wider publicity, but perhaps none of these is as basic to the needs of modern civilization. The objectives of the IHD are to foster international collaboration and cooperation in hydrology and to take stock of the world's freshwater resources, to increase the effectiveness of research into such problems as floods and the effect of man on the hydrological cycle, and to improve the knowledge needed for the future management of water resources.

The IHD started in 1965 and was the outcome of an idea conceived in the early 1960s. At a preliminary meeting, representatives of fifty-seven nations agreed that their governments should support the United Nations Educational Scientific and Cultural Organization (UNESCO) in launching an international cooperative programme in hydrology; now the IHD involves more than 100 countries as well as other international organizations such as the Food and Agriculture Organization of the United Nations (FAO) and the World Meteorological Organization (WMO). More than fifty technical items appeared in the original programme, and these included improving methods of measuring the basic factors of precipitation, evaporation and river discharge and making more effective use of maps for hydrological purposes. Proposals were made for standardizing methods of observation, for training and educating hydrologists in developing countries and for giving support to symposia on important topics. Progress up to 1969 was reviewed at the Mid-decade Conference, which was held in Paris in the December of that year, and both the programme for the remaining five years and plans for hydrology after the conclusion of the decade were also discussed. This question is now being considered by a special working group set up to make proposals for a long term UNESCO based programme in scientific hydrology. One problem is how to devise a means of fostering hydrology internationally, which is not just a revamping of IHD ideas spread over a longer time; another is that developing countries have special needs that may not be catered for in an intensely scientific programme. There are also the roles of the other UN agencies to be considered and the position of the International Association of Scientific Hydrology (ASH), one of the members of the International Union of Geodesy and Geophysics (IUGG). The FAO, for example, has its special interest in applying hydrology to the betterment of agriculture and the WMO is embarking on its own programme for operational hydrology. What is more, the meeting of the World Meteorological Congress in April 1971 gave consideration to the Organization's future role in hydrology and discussed to what extent it should cater for the needs of hydrological services in addition to those of the meteorological services. The question really is whether the WMO should become the World Hydrometeorological Organization at some future date. There are hydrometeorological services in a number of countries such as Sweden and the USSR, and these could be the basis of an obvious extension for WMO. Another possibility would be to found a new UN agency with interests spanning the entire field of hydrology and water resources. This would avoid the apparent "takeover" of hydrology by an allied discipline or the alternative—that it becomes an insignificant part of the programme of a large UN agency. On the other hand, there is the important question of finance and the fact that UNESCO, WMO and FAO and possibly WHO, the International Atomic Energy Agency (IAEA) and the UN Water Resources Development Centre would find it exceedingly difficult to divorce themselves from their present responsibilities in these fields.

Divided Responsibilities

It may seem rather odd that these international complexities have a parallel in Britain, but here too the responsibilities for water are divided. Depending on whether the fluid is considered a commodity, a danger, as a means of transport or as a subject demanding attention from the research worker, different bodies are involved. Water undertakings, sewage disposal authorities, government departments, the Central Electricity Generating Board and British Waterways have their own, sometimes competing, interests, to say nothing of industry, agriculture and those who think of water for sport, recreation and as an amenity. As a rule the unit of operation is small. In England and Wales there are more than 200 water supply undertakings, 1,300 sewage disposal authorities and 26 river authorities. As far as research is concerned there are 20 or more government bodies involved, as well as the universities. In fact the recent Natural Environment Research Council (NERC) Survey of Hydrological Research in the United Kingdom[2] revealed a tremendous wealth of research, much of it long term, being undertaken in a wide variety of establishments. One suggestion is that the most substantial parts of this research should, in future, come under the aegis of a new Central Water Authority[3]; but in view of NERC's existing statutory responsibilities and present commitments for research in hydrology, perhaps a strengthening of these responsibilities and better coordination centred on NERC would be a more appropriate solution.

Of course, it could be argued that the organization of hydrology, whether nationally or on a global basis, has little relevance to the drought stricken Indian village or the wide areas which the Danube has flooded. Yet the sharing of a river basin with other nations is in itself a compelling reason for international cooperation. Hence there are commissions or some form of control body for a number of the world's principal rivers, the countries concerned often being assisted by one or more UN agencies. Then there is the need to standardize instruments, methods of observation, methods of data processing and analysis so that hydrological information knows no frontiers. For example, there are considerable differences in the instruments used in various countries for the measurement of rainfall and evaporation—two basic elements in the water balance. To produce a rainfall map of Europe is an extremely difficult task, the most important reason being that each country uses its own type of gauge, which often differs radically in size, shape, material and method of installation from those used by its neighbours.

Evaporation is even more of a problem, for few countries have widespread networks of evaporation pans or tanks and some have none of these instruments at all. Not many have the detailed records of climate that are needed for determining evaporation indirectly, by the Penman method for example. There is a comparison of evaporation pans and tanks sponsored by WMO in progress at the moment. A number of meteorological stations around the world, for example Kew Observatory, have been equipped with US National Weather Service Class A pans, the GGI 3000 and 20 m^2 pans of the USSR Hydrometeorological Service and several other types of instruments; a number of years of data has now been amassed. A similar but unsatisfactory series of comparisons of rainfall gauges has been based on the Interim Reference Precipitation Gauge; unfortunately this type of instrument, a 1 m high gauge fitted with a wind shield, was as susceptible to aerodynamic effects as any other type of elevated gauge—these effects cause acceleration of air moving over the top of the gauge and consequently a diversion of drop trajectories away from the orifice. This problem can be almost completely overcome by installing a gauge in a shallow pit so that its rim is level with the ground surface and surrounding the gauge with an anti-splash grid. Proposals for a project based on this type of gauge were made at a WMO meeting at the Institute of Hydrology in July 1970 and the comparison of national rain gauges with these instruments commenced in June this year. Tests of these ground level gauges have been carried out in some countries already. In the USSR, comparisons of national standard gauges and ground level gauges made at a large number of sites have resulted in the re-drawing of precipitation maps and an upward scaling of values. Results from a number of sites in the United Kingdom indicate that the existing 1 foot high standard gauge network measures less rain than actually reaches the ground. Annual rainfall totals are between 3 and 7% greater than those recorded over most of south-east England, while the deficit can be up to 20% for unfavourable sites in the north and west.

Basin Programme

One of the most successful aspects of the IHD has been the representative and experimental basin programme which has aided the improvement of basic countrywide hydrological networks in less well developed countries and has been a stimulus to research in the more developed ones: these studies of complete catchments and their water budgets highlight the need for specialized instruments and improved methods of data processing and analysis. Several countries have planned their networks of representative and experimental basins; the one designed to sample the principal hydrological regions and the other to sample the chief changes in the use of land. In others, Britain for example, the growth of these catchment studies has been rather haphazard. A survey of basin studies undertaken by NERC in 1968 showed that there were almost fifty such projects in progress within the United Kingdom. Certain parts of the country and certain objectives were adequately covered, for example studies of the effects of afforestation in upland Britain. On the other hand, there were only two studies being undertaken in lowland England on the consequences of urbanization—one of the most radical of all land use changes. The hydrological significance of snow, particularly in the Scottish Highlands, was also not being investigated—quite a serious gap which still remains.

The situation in Australia is rather different. About eighty physical regions have been delimited using indices of geomorphology, geology and rainfall, and a representative basin is being established in each[4]. Various government organizations and universities are participating in these activities which are being promoted by the Department of National Development. Records from each basin are being assembled in computer compatible form and will be made available to the CSIRO Division of Land Research, Canberra, for analysis. For the analysis, a rainfall-runoff model has been devised[5] and tested with data from a basin near Alice Springs. Predictions of storm runoff are produced from observations of rainfall, potential evaporation and a number of other factors.

The New Zealand network of representative basins has also been planned rationally[6]. The two islands have been divided into about ninety hydrological regions, a representative basin being established in nearly all of them by the Water and Soil Division of the Ministry of Works. These catchments sample the principal precipitation zones, the chief soil types and the important geomorphological areas; they range in size from 1 to 250 km^2. There are also a number of experimental basins in operation such as those at Moutere near Nelson, where the significance of various changes in land use is being studied in twelve small catchments[7]. One experiment at this site is concerned with cultivating a gorse catchment and studying the resulting change in the water budget and the differences in the distribution of stream discharge. Peak flows were found to increase, annual runoff totals were nearly doubled, but there were fewer days when runoff occurred. This and similar studies are particularly important for New Zealand, where immense

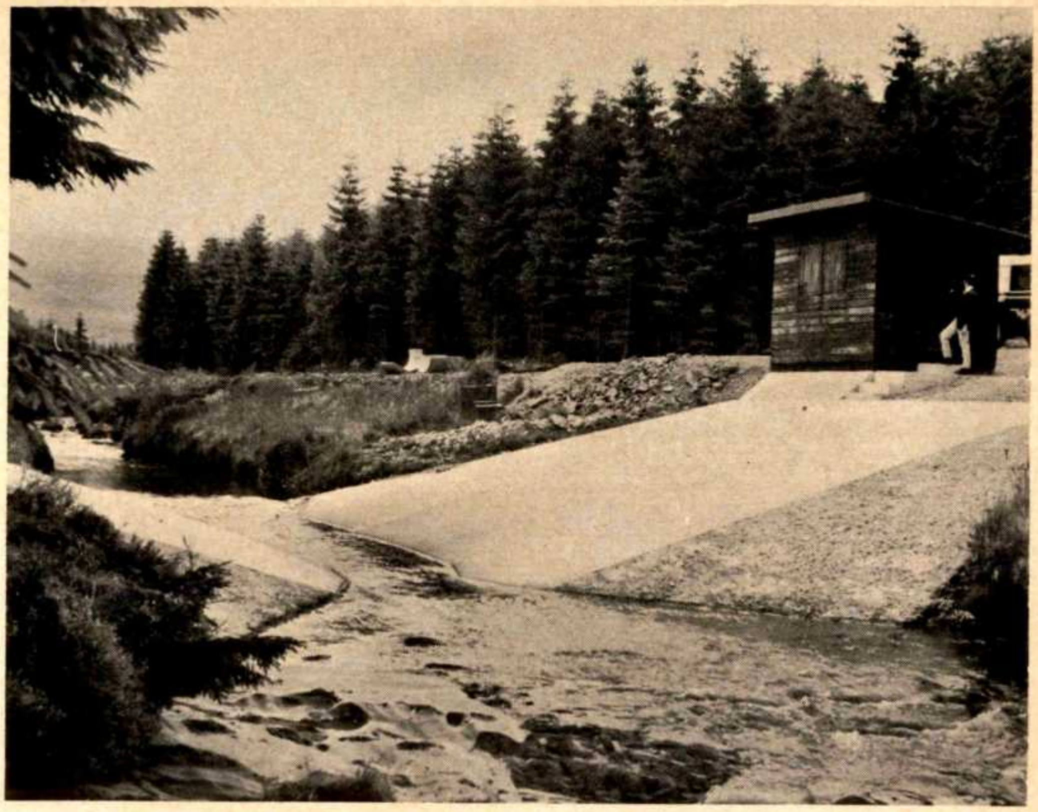


Fig. 1 Trapezoidal flume used by the Institute of Hydrology for gauging flows from the forested headwater catchment of the River Severn in the Plynlimon experimental catchment where the hydrology of forest and upland sheep pasture is being compared.

problems have resulted from imported land use practices and their effects on soils and water.

Measuring Advancement

The nature of these problems and the strenuous efforts being made to find solutions to them may have been one of the reasons for holding in December 1970 the symposium on the results of research on representative and experimental basins at Wellington, New Zealand. This symposium, organized by the Royal Society of New Zealand and arranged by the International Association of Scientific Hydrology with the support of UNESCO, was attended by over 150 hydrologists from more than thirty countries. Earlier in the year, the World Water Balance symposium had been held at Reading University and had attracted more than 250 participants from about fifty countries. After the Symposium about sixty of the participants went on a tour of Central Wales and the Midlands. One of the sites visited was the Institute of Hydrology's Plynlimon Catchments, where a long term study of the contrasting headwater basins of the Wye and Severn was commenced in 1967. The basin of the Wye is almost entirely sheep pasture, while the adjacent Severn is nearly all planted softwood forest—an ideal situation for investigating the hydrological consequences of these land use differences. For large areas of upland Britain are being afforested, but the effects of this change in land area river flows are not clear. Are floods reduced in severity? Do flows diminish more rapidly during dry periods? By measuring rainfall, evaporation, and changes in soil water storage, in addition to river flows, it is anticipated that the magnitude of any alterations to the hydrological regimes of these areas can be established, as well as the causes. Data are now being collected from specially constructed river gauging stations in the two basins (Fig. 1) and from fifty rain gauges and fifty soil moisture sites distributed over the catchments. Five automatic weather stations will be installed shortly for assessment of evaporation to supplement the two conventional stations that have been operating for some time. Initial results show that there are substantial differences between the two areas that must result from the contrasting land usage. Both the Reading and Wellington meetings took place within the framework of the IHD and they provided valuable forums for the exchange of ideas and the promotion of contacts between individuals. Indeed it has been said that the IHD has been better for hydrologists than for hydrology, but it is difficult to see how the benefits can be separated.

Measurement of the advancement of a science is not, of course, an easy task; progress is never continuous but rather a series of breakthroughs and periods of consolidation. Sherman's inceptive unit hydrograph paper[8] was the breakthrough in the 1930s, followed by Gumbel's work[9] on extreme value theory and Penman's studies of evaporation[10] a decade later. But similar progress after 1950 is difficult to pinpoint in the same way. Perhaps the computer revolution and particularly the spate of mathematical models of catchment behaviour that has resulted is one of the most noteworthy features. Advances in methods of analysis have certainly been rapid recently, so much so that faults in the basic measurements are becoming one of the chief hindrances to further progress. Britain seems to be well placed, for there are few countries with equal experience in instrumentation, particularly in rainfall measurement, stream gauging and soil moisture assessment. It could even be argued that the problems resulting from Britain's relatively recent start in scientific hydrology are rapidly being overcome. Hydrology is now an established science, a science that is extremely valuable to the community at large, though not one that captures the interest it deserves.

Prospects for Carbon Fibres

R. JEFFRIES

The Cotton Silk and Man-made Fibres Research Association, Shirley Institute, Manchester

The relatively high price of composites reinforced with carbon fibres still means that they will only be used when their strength, stiffness and lightness are absolutely essential. But in the future, industries as diverse as the chemical industry and shipbuilding could reap the benefits of a cheaper product.

CARBON fibres made from cellulose fibres have been known for a considerable time. They were not sufficiently strong or stiff to be of any real value for the reinforcement of composite materials and were manufactured for their thermal insulation and ablative properties, and for use in filter beds and so on. A team at the Royal Aircraft Establishment (RAE) first made carbon fibres with tensile properties good enough to warrant the term "high performance" in relation to reinforcement[1,2] and at about the same time, at the Aero Engine Division of the former Rolls-Royce Ltd, similar techniques were also being developed for producing these high performance carbon fibres; rapid progress was made in translating this laboratory work into engineering practice. The RAE and Rolls-Royce carbon fibres are produced by the controlled thermal degradation of a special grade of acrylic fibre made by Courtaulds Ltd (for example refs. 2–5). In the three-stage heating process (for example refs. 2–7) the fibre is first oxidized by heating in air at 200° to 300° C; it is then carbonized by heating in an inert atmosphere to about 1,000° C and finally the carbonized fibre is graphitized to a greater or lesser extent by heating (also in an inert atmosphere) to a temperature in the region 1,500° to 3,000° C. Carbonization removes almost all nitrogen and hydrogen from the acrylic fibre and a proportion of the carbon, leaving a fibre made substantially from carbon—hydrogen cyanide and ammonia are the chief gases evolved[8–13]. Graphitization "crystallizes" the carbon fibre to some extent, that is it causes the carbon structure to organize itself into a more regular arrangement similar to (though not the same as) natural graphite. The mechanical properties of the final fibre depend on the temperature of the graphitization stage of the preparation process and it is therefore possible by this means to produce different types of carbon fibre.

An important feature of the process is the maintenance of the high orientation in the acrylic precursor throughout the carbonization processes[2,3,5]; to this end, tension is applied to the fibre during the early stages of the process to prevent any shrinkage and structural disorientation. It is partly the use of tension which distinguishes the process of Watt and his co-workers from that of Shindo[8] who also studied the preparation of carbon fibre from an acrylic precursor.

Each stage of the heating programme has presented considerable development problems, particularly in turning the process into a large scale operation; for example, the oxidation stage is exothermic in character and liable to get out of control[6].

These problems were solved, however, and production of the fibre in commercial quantities has been under way for some time. Two forms of process have been developed: in the first the material is prepared by a batch process, in which carbon fibres are produced with lengths of about a metre. A continuous process has more recently been developed which yields material with lengths up to about 1,500 m.

Properties and Performance

High performance carbon fibres are black, lustrous, rather slippery to handle and are at present produced with diameters of 8 to 9 μm (ref. 3). Their mechanical properties are outstandingly good (Table 1, from refs. 1, 14–17) and values quoted by other manufacturers of carbon fibre (Rolls-Royce, Courtaulds, and Morganite) are all similar in magnitude. Each value of strength and modulus in Table 1 is divided by specific gravity to give the specific strength and modulus; these specific values should always be considered when comparing materials on a weight for weight basis. The carbon fibres (both the high strength and high modulus types) are far superior to the steel. The glass fibres (particularly the S type) are similar in strength to the carbon fibres but have a much lower modulus. It is this very large stiffness that makes carbon fibre such an important reinforcing material for engineering applications; high strength needs to be associated with high modulus (that is, high stresses have to be borne at low extensions) in most engineering materials. The carbon fibres show completely elastic behaviour up to the breaking point and so there is no irreversible extension or creep. The fibres are comparatively weak and of low modulus in the direction perpendicular to the fibre axis; for instance, the Young's modulus of graphite at right angles to the graphite planes is only about 5×10^6 pound inch^{-2} (ref. 18).

As the temperature of the third stage of the heat treatment[16] is increased in the range of 1,000 to 2,500° C the modulus steadily increases and the tensile strength at first increases, reaches a maximum at about 1,500° C, and then decreases. It is thus possible to prepare a high modulus fibre, at the expense of some strength, or a high strength fibre at the expense of some modulus. The difference between the "high modulus" and "high strength" fibres in Table 1 arises from the differences in the temperature of the final heat treatment. Courtaulds and Morganite manufacture both high modulus and high strength fibres; Courtaulds type HT and Morganite type II are high strength, Courtaulds type HM and Morganite type I are high modulus. Courtaulds also make a Type A fibre which is of somewhat lower strength and modulus than the type HT, but has certain other advantages that will become clear later[3].

The standard deviation of the strength values of carbon fibres is about 25% (refs. 1 and 14); this is because of structural flaws which cause premature breakage. By comparison, the Young's modulus of the fibre, being an intrinsic property of the fibre and therefore not influenced by flaws, is much less variable and the standard deviation is only about 5% of the mean. Flaws of a discrete, "macroscopic" nature may, however, be the strength-controlling factor only for carbon fibres prepared at temperatures up to 1,300° C (refs. 19 and 20); at higher treatment temperatures some other strength-controlling mechanism seems to take over. It has been suggested[21] that the strength of the fibres may be governed in some circumstances by microcracks formed during cooling from the processing temperature.

Carbon fibres are very resistant to heat in inert conditions and the volatilization temperature is more than 3,000° C; they begin to oxidize in air at 410 to 450° C, however. The thermal and electrical conductivities along the length of the fibre are lower than the values for a heat treated pyrolytic graphite in the direction parallel to the planes in the graphite structure[22], showing the effect of the small crystallite size in the fibres.

Fibre Structure

The structure of carbon fibres is similar to that of graphite—the atoms are in layers or planes and the planes are arranged almost parallel to each other. In true graphite, however, the atoms in each plane are arranged in a regular manner with respect to those in the adjacent planes, but in carbon fibres there is no such regular arrangement and the structure is described as turbostratic[22].

The planes of atoms are well oriented in the direction of the fibre axis[1]—in the case of a high modulus fibre to within 10° of the axis. This high degree of orientation is the reason for the high modulus of the fibres[1], and any treatment that increases the orientation invariably increases the modulus, regardless of whether the increased orientation is imparted by stretching the precursor acrylic fibre[23,24], by the application of tension during the oxidation stage[25,26], or by stretching the final carbon fibre during the graphitization process[27-29].

Table 1 Comparison of Properties of High Performance Carbon Fibres with Other Materials

Property	RAE carbon fibre High modulus	RAE carbon fibre High strength	Steel wire	S-glass fibre	E-glass fibre	Bulk steel	Bulk aluminium	Bulk titanium	Cotton	Textile viscose	Polyester fibre
Tensile strength (10^3 pound inch^{-2})	300	430	400–600	650	500	145	67	135	70	40	90
Extension at break (%)	0.5	1.3	~2	~5	~5				9	20	22
Young's modulus (10^6 pound inch^{-2})	60	33	30	12.5	9	30	10.5	16	0.6	1–2	1.8
Specific gravity	2.0	1.74	7.8	2.5	2.5	7.8	2.8	4.5	1.55	1.51	1.38
Specific tensile strength	150	250	51–77	255	200	18.5	24	30	45	26	65
Specific Young's modulus	30	19	3.8	4.9	3.5	3.8	3.75	3.5	0.4	0.65–1.3	1.3

The carbon fibres are composed of aggregates of crystalline regions separated by grain boundaries and pores. These crystallites in graphitized fibre are thought to be about 40 to 100 Å wide[21,22,30,31] and about 60 to 120 Å long in the fibre direction[21,22,30]; the dimensions are somewhat less in ungraphitized carbon fibre[22,31,32]. This polycrystalline nature has already been mentioned in connexion with the electrical and thermal conductivities of the fibres.

The specific gravity of RAE carbon fibres (Table 1) is much lower than that of true graphite, which is about 2.26. This may be partly the result of imperfect graphitization but is more likely to reflect the presence of a pore structure in the fibre. Johnson and Tyson[30] consider that the voids separate the short crystals in the graphitized material, and have a mean width less than 10 Å.

There is evidence[21,22,33] that RAE carbon fibres have some fibrillar character and the suggestion has been made that the strength of the fibre is a function of the interfibrillar bonding. Evidence has recently been adduced that sheet-like structures are also present in carbon fibres[33].

Composites

If the exceptional properties of carbon fibres are to be utilized for engineering purposes they must be fabricated as a "reinforced plastic"; the fibres are aligned in the required direction or directions and embedded in a suitable resin. There are three types of technique for preparing "directional" composites[34-36]. In the "leaking mould" technique, the fibre is combined in the mould with a solventless liquid polyester or epoxy resin and then pressed; the excess resin is forced out of the leaky mould. In the "prepreg" method, layers of fibre are impregnated with heat-setting resin in dilute solution and dried. These preimpregnated layers are then moulded together in the normal way under heat and pressure, and cured. Filament winding techniques involve the building up of layers of fibre (intermixed with resin) by winding the fibre onto a rotating former; more or less continuous lengths of fibrous material are obviously needed for this technique. Random composites are made by mixing chopped carbon fibre with resin and subjecting the mixture to the usual moulding techniques.

The mechanical properties of the carbon fibre-resin composite depend on the mechanical properties of the fibre, the volume fraction of the fibre in the composite, the orientation of the fibre in the composite, and the strength of the fibre-resin bond. Phillips[35] has described the various properties of unidirectional composites (those containing fibres oriented in only one direction) made with RAE high modulus fibre and a polyester resin at a volume fraction of fibre of about 40% (50% by weight). The properties in the direction of fibre orientation, as listed by Phillips[35], are shown in Table 2. In spite of the diluting effect of the resin, the specific strength and modulus values of the composite in the direction of fibre orientation are still much superior to that of any of the three bulk metals in Table 1. The modulus and flexural strength of the composite are almost unaffected by immersion in cold or boiling water[37]—the carbon fibre-resin interface is weakened by less than 5%, whereas the interface between glass fibre and resin is weakened by as much as 15%. The fatigue life of the composite is very good, and the damping properties are also good. The properties of carbon fibre reinforced plastics, made with Courtaulds and Morganite carbon fibres, and also with carbon fibres produced in the United States have been summarized by Dauksys and Ray[38].

The properties of carbon fibre reinforced plastics depend to some extent on the strength of the bond between the fibre and the resin. Too weak a bond leads to a low interlaminar shear strength (ILSS) whereas too strong a bond causes the

Table 2 Properties of Carbon Fibre–Resin Composites

Property	Unidirectional carbon fibre–resin composite[35]	Bulk steel	Bulk aluminium	Bulk titanium
Tensile strength (10^3 pound inch^{-2})	105	145	67	135
Young's modulus (10^6 pound inch^{-2})	22	30	10.5	16
Specific gravity	1.54	7.8	2.8	4.5

material to be brittle; a compromise has therefore to be reached[38,39]. The ILSS of carbon fibre reinforced plastic made with untreated carbon fibre (particularly high modulus fibre) is lower than is desirable for many purposes but both Courtaulds and Morganite now market both high modulus and high strength fibres that have been specially treated to improve the fibre-resin bond and thus increase the ILSS. Courtaulds also market a carbon fibre which, although somewhat less strong and stiff than the other two types, produces composites of satisfactory ILSS even without treatment; it is cheaper than the other types, and has a breaking strain of more than 1% which is advantageous for some purposes. An alternative means of increasing the ILSS is to whisker the carbon fibres, that is, to cover the fibre with large numbers of randomly oriented, short whiskers[40,41]. Giltrow and Lancaster[42-44] have shown that the presence of carbon fibre in a resin reduces the coefficient of friction and rate of wear.

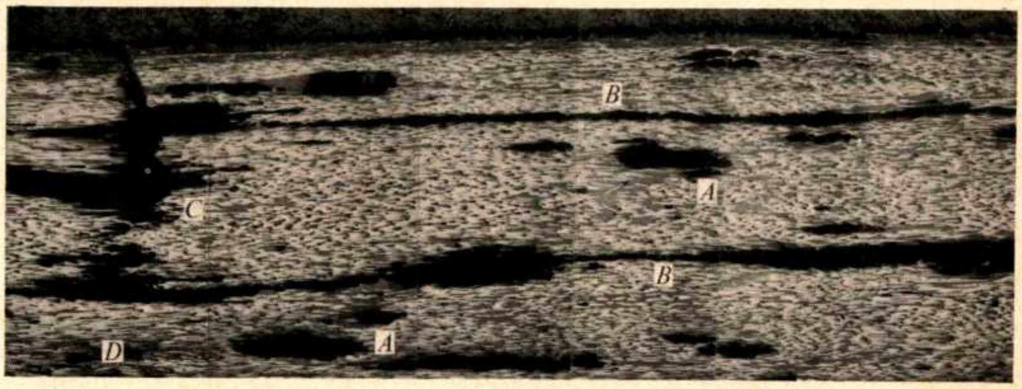

Fig. 1 Photomicrograph of a longitudinal section of a carbon fibre resin unidirectional composite tested to failure.

Fig. 1 shows a photomicrograph (at a magnification of about 40) of a longitudinal section of a carbon fibre resin unidirectional composite tested to failure in a three-point short-beam bending test; the composite contains 60% of fibre in an epoxy resin. The photomicrograph illustrates the various faults that can be present in this type of composite as manufactured (this is, in fact, a poor specimen of composite chosen to reveal these various faults), and also the additional features which appear as a result of stressing the composite to failure in this type of test. In the photograph, the fibres show up white, the resin grey, and voids and cracks appear black. The three types of fault present in untested specimens are voids (marked A in the photograph), places where the concentration of fibre is very low, and misaligned fibres. Each of these faults are potential weak points in the composite, particularly the voids; it is likely that, in the case of this specimen, the failure mechanism originated at voids. When a composite is tested in the three-point test, the specimen first fails in shear, and the long cracks (B) are the result of this type of failure. Further stressing of the specimen leads to compressive failure, characterized by the crack (C) perpendicular to the fibre direction. In some instances of tests of this type, tensile failure near point D takes place.

The incorporation of carbon fibres into magnesia, glasses and aluminium is being investigated[45] and there is thus a possibility in the future of toughened ceramics and metals. One difficulty in the reinforcement of metals with carbon fibre is the tendency for a chemical reaction to take place. This difficulty can be overcome by coating the carbon fibres with a barrier layer of an unreactive third material (for example, tungsten[46]).

Development Potential

Whiskers of graphite, prepared for example by a high pressure carbon arc technique[47], have extremely high tensile properties; tensile strengths of 3×10^6 pound inch^{-2} and a Young's modulus of 100 to 130×10^6 pound inch^{-2} have been achieved[47], but it has been estimated that the theoretical strength and modulus of the graphite crystal are 14.5 to 20×10^6 and 145×10^6 pound inch^{-2}, respectively[48]. There is therefore ample room for development in the tensile properties of the acrylic based carbon fibre, particularly in the strength. Whiskers are, however, almost continuous crystals of graphite, whereas carbon fibres are polycrystalline and will therefore suffer from inherent limitations in strength and modulus as a result of the structural imperfections associated with the crystallite boundaries.

Carbon fibres made from acrylic precursor fibre are by no means the only form of carbon fibre available. Carbon fibres made from cellulose have been available for many years and, though of relatively modest tensile properties, they have attributes that make them suitable for a range of applications (for example, thermal insulation). Union Carbide have improved the orientation, and thus the mechanical properties, of cellulose carbon fibres by stretching them during graphitization at more than 2,000° C; these stress-graphitized fibres (the Thornel fibres) have mechanical properties not too far below those of acrylic based carbon fibres.

Why have only acrylic and cellulose fibres been used on any large scale as precursors for carbon fibres? Although a complete answer to this question is not possible, the basis of the answer is probably reasonably well understood. The organic fibres that can be carbonized fit into two groups: those that give a carbon fibre that is graphitizable and those that give a carbon fibre that is not in reality these are probably two extremes, with all carbon fibres lying somewhere in between. The graphitizable carbon fibres probably have superior tensile properties (after heating to graphitizing temperatures) than the equivalently heated non-graphitizing carbon fibres[49]. Carbon fibres from acrylic fibres are graphitizable and this is probably one reason for their superior tensile properties. But why are they the best of the currently available graphitizable carbon fibres? The answer probably lies, partly at least, in the high orientation of the acrylic based carbon fibres, which in turn originates in the particular nature of the chemical reactions taking place in the acrylic degradation process (principally in the oxidation stage under tension). These reactions stabilize and preserve the orientation during the later stages of the heating process.

Carbon fibres are being produced from precursors other than organic fibres, however. The Kureha Company in Japan, for example, makes carbon fibre from pitch. The Kureha fibres available are, however, of low orientation and have similar mechanical properties to glass fibres (that is, they are of comparatively low modulus). A research group at the University of British Columbia are also producing carbon fibres from low cost pitch materials: excellent mechanical properties (similar to those of acrylic based carbon fibres) have been reported for pitch based fibres that have been stretched during graphitization at 2,000° C to 2,800° C (ref. 50). The British Coal Utilization Research Association's Industrial Laboratories are making strong carbon fibres from coal products and fibres stronger than E-type glass fibre have successfully been prepared[51].

Composite Applications

The most likely immediate applications for composites reinforced with carbon fibres are those in which their combination of strength, stiffness, and lightness is at a premium and in which the cost of the material is less important[34–36]. The aircraft and space industries meet both these conditions and will, no doubt, provide numerous applications in the future for carbon fibre reinforced plastic, despite the much discussed difficulties with the fan blades of the Rolls-Royce RB211 engine. It seems likely that several other aircraft components (helicopter blades, aircraft structure parts, aircraft containers and so on) will also eventually be made from carbon fibre reinforced plastic. The advantages of carbon fibre reinforced plastics over metals in space vehicles (for example, rocket motors and satellites) are particularly obvious because of the large amount of fuel needed to put a small weight into space.

The cost of carbon fibres, and difficulties in the use of composite materials for some purposes, have restricted the number of "earthbound" uses of high performance carbon fibre. At the Atomic Energy Research Establishment, Hanwell, carbon fibre composites have been used in chopper disks in neutron experiments[3] and Dowty Rotol Ltd make fan blades from the material[52]; Bonas Brothers use carbon fibre reinforced plastic to make a special component for a high speed loom[53]. The high strength and stiffness of RAE-type carbon fibre has also been utilized with benefit in the panels of the Ford GT40 sports car.

This present rather limited use of carbon fibre reinforced material is, however, a phase that will soon pass, and there is no doubt that in the not too distant future the use of the material will expand rapidly. Some possible applications include the manufacture of boats and submarines for which the fact that carbon fibre composites are little affected by water is a particular advantage and pressure vessels of all types. The relative chemical inertness of carbon makes the use of carbon fibre composites of considerable potential value in chemical plant environments that are severe, both chemically and physically[54]. Any engineering device involving rotating members will obviously be improved if manufactured from carbon fibre reinforced plastic, because the centrifugal forces in the rotating part depend on the weight of the part. There are also improvements to be gained in the manufacture of wires and cables for high stress-bearing situations and engine components for high performance internal combustion engines. Composite material containing chopped fibre has also been shown to have excellent friction and wear characteristics[42–44]. The high strength and modulus of carbon fibre reinforced plastic allows a good balance to be achieved on sports equipment—adequate strength can be allied to a proper distribution of weight.

Research at Shirley Institute

Certain aspects of the development work on carbon fibres and composites have clearly required knowledge and expertise of a textile, rather than engineering, character. For this reason both the former Ministry of Technology and the former Rolls-Royce Ltd sponsored research work on carbon fibres at the Shirley Institute. This many sided research is confidential in nature and it is only possible to mention briefly two pieces of work. The first, performed under contract to the Ministry of Technology, is the development of a novel method for spinning yarns from the comparatively short lengths of carbon fibre produced by the batch process. Ordinary textile machinery and processing could not be used because the carbon fibres are too smooth and slippery. Work was also carried out under contract to the former Rolls-Royce Ltd on the development of a new weaving method for assembling filaments into a wide, flat, continuous sheet.

The Institute now possesses widely based expertise and facilities for research on carbon fibres and composite materials, and is continuing a high level of effort in this field, both in its general research programme and in the rapidly expanding sponsored sector of its activities.

I am grateful to the Composite Section of Shirley Institute for the photomicrograph of the tested specimen of composite.

New Hominid Skull from Bed I, Olduvai Gorge, Tanzania

M. D. LEAKEY, R. J. CLARKE & L. S. B. LEAKEY

Centre for Prehistory and Palaeontology, PO Box 30239, Nairobi

Restoration of a hominid skull recovered from Bed I at Olduvai Gorge has revealed it to be a member of the genus *Homo*. Although the new cranium resembles *H. habilis* from Bed II, it differs in some respects from the type of *H. habilis* from Bed I. This may be a case of sexual dimorphism.

THE cranium described by L. S. B. L. later in this article (Olduvai Hominid 24) was found by P. Nzube in October 1968 (ref. 1) at a site in Olduvai Gorge that lies in the eastern part of the gullies known as DK, approximately 300 m east of the living site in lower Bed I that was excavated during 1962 and 1963.

The Site

The cranium was embedded in a mass of calcareous matrix measuring approximately 20 × 12 × 8 cm. All the bones were covered by matrix with the exception of a small portion of the right supra-orbital region and the posterior part of the palate. Indeed, so few identifiable parts were visible that it is remarkable it was recognized as hominid. The deposit on which it was found consists of a tuffaceous clay that can be traced over a wide area in Bed I, extending from the eastern part of the Gorge as far west as the FLK sites. This horizon overlies the basalt and is in turn overlain by the marker tuff IB for which an apparently reliable average date of 1.8 m.y. has been obtained by K/Ar dating[2]. At the hominid site (DK East), the tuffaceous clay is 3 m thick but the thickness varies considerably at different localities, depending on the surface configuration of the underlying lava. The clay at several other sites has yielded artefacts and fossil bones, including the molar tooth of Olduvai H. 4, found at MK during 1959, that has been attributed to *Homo habilis*[3] as well as the only remains of a chalicothere known from Olduvai.

After the discovery of the cranium the surface deposit was sieved extensively and an area of approximately 400 m^2 was eventually worked over. Three complete and some broken teeth were recovered as well as substantial portions of the maxillae, part of the occipital, several fragments of the parietals and the left supra-orbital region of the frontal bone. Some fragments were found low down the erosion slope and at a depth of just under 1 m from the present ground level: others lay on the surface, close to the block of matrix containing the cranium. It is evident that the specimen had been exposed for many years and that, as fragments broke off, some rolled down the slope and were buried under hill wash, while others became detached more recently and remained on the surface near the parent block. No trace of the canine and incisor teeth was found and it is likely that they broke off first and were transported downhill by erosion, possibly as far as the present river course.

The matrix in which the cranium was embedded is indistinguishable from the limestone concretions that frequently occur within the tuffaceous clay that overlies the basalt at DK and elsewhere (the mandibular fragment containing the molar of Olduvai H. 4 was similarly embedded). These concretions often form round fossil bones that can be seen as central cores when the blocks are broken open.

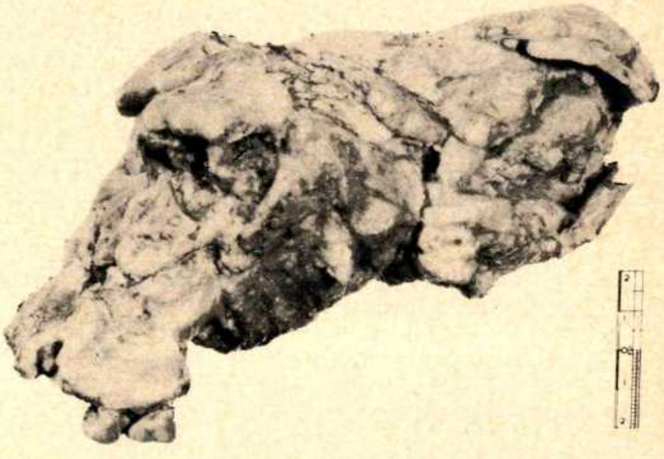

Fig. 1 Cast of Olduvai H. 24 after partial cleaning and before reconstruction.

Crocodile remains predominate among the faunal material from this site and more than 2,000 teeth were found. Tortoise plates, shells of Urocyclid slugs, fish vertebrae and scales, bird bones and pieces of ostrich eggshell were also relatively common. Mammalian bones and teeth included those of primates, rodents, carnivores, equids, suids, giraffids and bovids. There were also more than 37,000 unidentifiable bone fragments. The state of preservation of these remains is very similar to that of the cranium and many were also found embedded in limestone concretions.

Associated Stone Industry

Apart from a few quartzite flakes and chips, no artefacts were found, but the living floor previously excavated at DK—which included the circle of lava blocks considered to represent an artificial structure—has yielded a large series of artefacts that represent the contemporary stone industry[4]. This site consists of a living floor within the same tuffaceous clay that occurs at DK East and is similarly overlain by Tuff IB. In some places the accumulation of occupation debris rests on the surface of the lava, so that the living floor is at a slightly lower level than the layer of limestone concretions from which the cranium is believed to have eroded. Artefacts recovered from the living floor and from the clay above amount to 1,198 specimens, consisting of 154 tools, 187 utilized pieces and 857 debitage. The industry is typical of the Oldowan as it occurs throughout Bed I. It includes choppers of various forms, generally made on water-worn lava cobbles, polyhedrons, discoids, sub-spheroids, heavy and light duty scrapers and burins. Although the tools are of the usual Oldowan types, a proportion of the choppers, polyhedrons and discoids are smaller than those from higher levels of Bed I.

The associated faunal material includes all the species noted at DK East with the addition of *Elephas* and *Deinotherium*. Crocodile remains are similarly the most numerous.

Restoration of Olduvai H. 24

The tools used by R. J. C. in the removal of matrix from Olduvai H. 24 were a chisel-ended dental pick and a small hammer, a diamond drill and an S. S. White Industrial Air–Abrasive machine. Acetic acid could not be used because although the exposed pieces of bone had become hardened by weathering, those not exposed were softer than the matrix. Parts of the matrix contained impressions of bone fragments that had fallen out during weathering. Some of these were found during excavation and it was possible to fit them back into position and thus build up the cranium into the form it had been before they became detached. It was apparent that the specimen was reasonably complete but had been badly crushed and distorted, the chief pressure having been downward and backward from the brow region, with the result that the nasal bones, although complete and perfectly preserved, were lodged down behind the infra-orbital region. The glabella, still attached to the nasals, was crushed, and the brow ridges were squeezed close together on top of the glabella.

The vault fragments were first separated and then completely cleaned of matrix under a binocular microscope. The facial fragments were more difficult to separate because they were interlocked and rammed against each other, but once they were free of matrix there were perfect joins between the nasals and the rest of the face and between the right brow ridge and the right orbital margin, just above the frontozygomatic suture.

The base of the cranium had been depressed into the brain cavity and was rammed against the right petrous, and the basioccipital had been pushed under the vomer.

After thorough cleaning, consideration of sutures, bone thickness and curvature it was found that all the vault fragments but one joined together and that there was contact from the foramen magnum almost to the glabella. The sides of the vault, however, were not present. The posterior part was

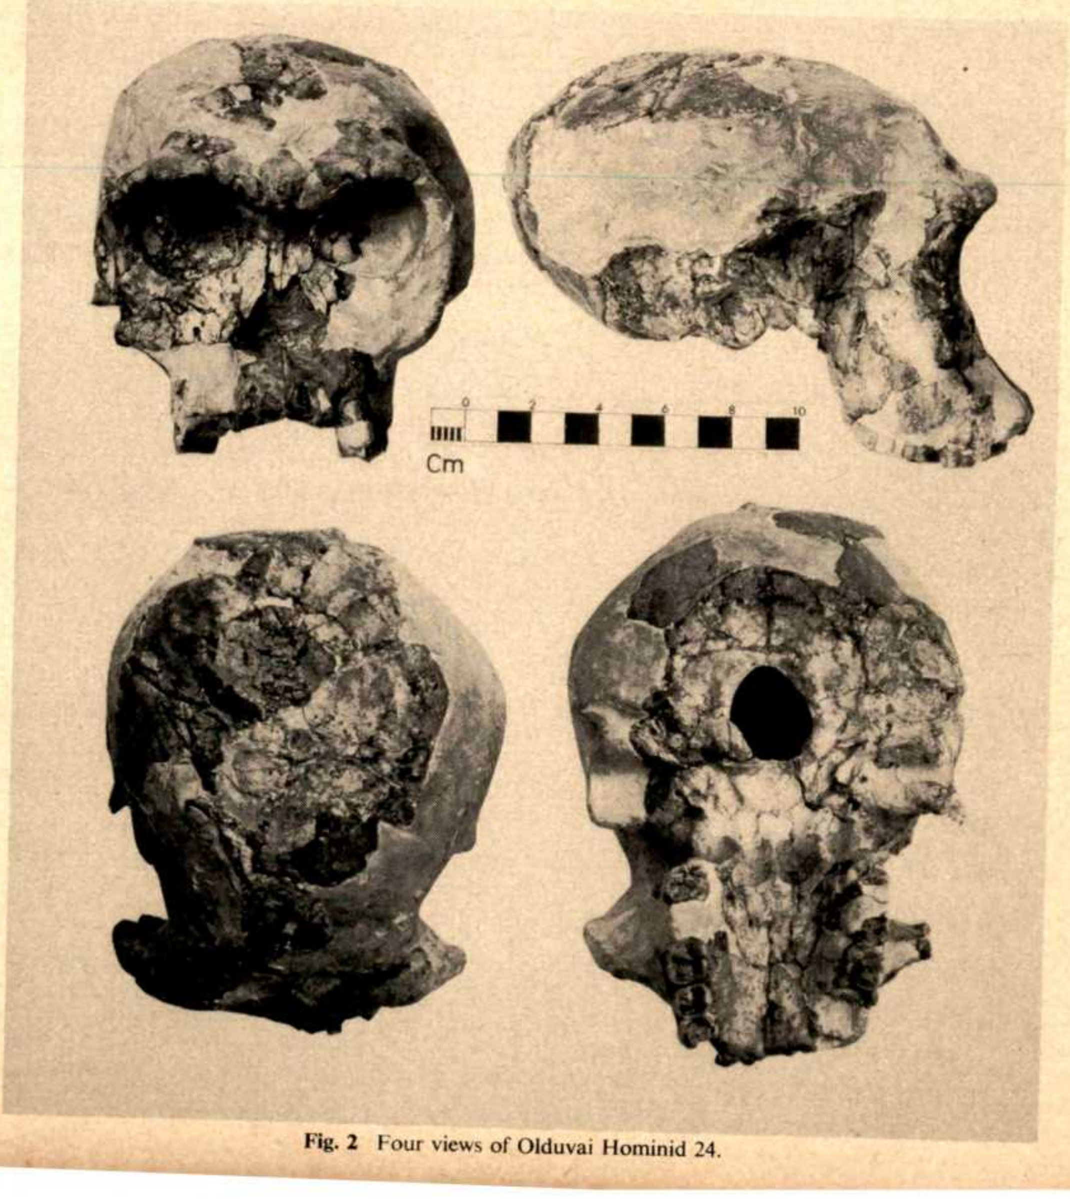

Fig. 2 Four views of Olduvai Hominid 24.

considerably crushed and in order for the joins in this region to lock properly it was necessary to straighten out the buckled lambdoid region by breaking through the bone along one crushed bend and by partially cutting and breaking the bone just above the suture.

The crowns of the left P^4, M^1 and right M^1 that were found during sieving fitted back directly on to the palate, but the left P^3 and the fragment of right M^2 had to be placed in position with plaster supports. A small but perfect contact between the mesiolingual fragment of the right M^3 and the major portion of this tooth could be seen under the microscope. The two pieces were fitted together and were placed in position on the palate by means of an impression that had been left in the matrix.

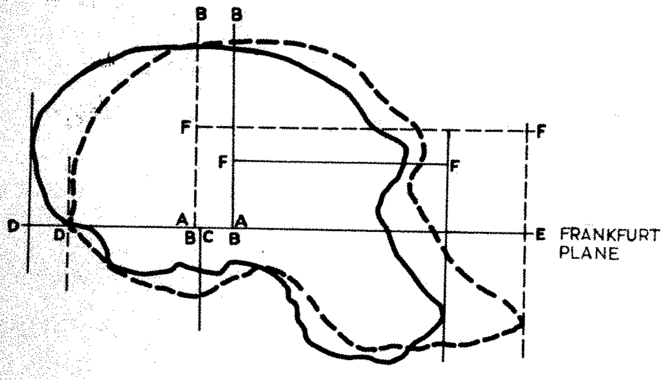

Fig. 3 Profile of Olduvai Hominid 24 (solid line) superimposed on that of *Australopithecus africanus* ST. 5 (broken line).

The cranium is still warped slightly and it is doubtful whether it can be completely straightened out, particularly as the sides of the vault are missing. The right petrous and tympanic plate are still in their crushed position and it would be a major operation to attempt to restore these bones to their proper relationship. The base of the cranium is also still depressed into the brain cavity and its thinness in places and the fact that it is covered with a network of fine cracks inhibit the possibility of restoration. The crushing of the whole cranium has also to be taken into account when considering the cranial capacity, which must inevitably have been greater than the absolute capacity as measured now.

Description of Olduvai H. 24

This specimen now consists of the following parts: almost the entire supra-orbital region of the frontal, the greater part of the vault, a considerable part of the occipital bone, nearly all the sphenoid, nearly all the right temporal bone and a considerable part of the face and palate, including the nasal bones. (Measurements are given in Tables 1 and 2.)

(1) The frontal bone. The supra-orbital region on the right side is almost intact as well as most of the glabella region. A large part of the left supra-orbital region is also preserved but it does not extend quite as far as the external orbital angle. There is also a small piece missing between the left supra-orbital fragment and the glabella region. On the right side the external orbital angle is intact and in normal articulation with the orbital process of the zygomatic. The supra-orbital region as a whole, while forward projecting, is not very massive. The glabella contact with the nasal bones at nasion is preserved and nasion lies well behind the overhanging glabella. Behind the supra-orbital region there is a depressed valley that is more pronounced above the glabella than on either side. In such parts as are preserved the frontal bone rises from this valley in a low curve towards bregma. There is sufficient of the frontal bone to be reasonably certain of the glabella–bregma length, which is approximately 90 mm.

On the right side of the cranium the region immediately behind the external orbital angle and the supra-orbital torus is well preserved. Part of this area is also present on the left side so that the minimum frontal width can be closely estimated. The figure is 75 mm.

(2) The parietals. Although neither of the two parietal bones is intact, the whole of the sagittal suture is preserved so that the bregma–lambda cord and arc can be measured with reasonable accuracy: these are 76.5 mm and 81.0 mm respectively. On either side of the sagittal suture the parietal bones extend laterally with only a slight downward curve for about 50 mm. Although the lateral parts of both parietals are missing, these bones must then have turned abruptly downwards if they were to meet the squamous parts of the temporal bones. This can clearly be seen on the more complete right side of the cranium. The sagittal suture is very largely fused but can still be traced. This condition is somewhat surprising in an individual whose third molars were barely erupted and not yet in occlusion. It suggests that the eruption of the third molars in early hominids based on analogy with modern man may not be a reliable indication of age.

(3) The occipital bone. A large part of this bone is well preserved, especially on the right side. There is enough of the nuchal area intact as well as continuous contact from lambda to opisthion to make a reasonable reconstruction of the upper half of the occipital and it is possible to estimate, with a fair degree of accuracy, the lambda–opisthion arc and cord: these measure 87.5 mm and 71.0 mm respectively. The arc/cord index (Martin's index 125)[5] is 81.14. By doubling the measurement from the right asterion to the midline of the occipital it is also possible to estimate the bi-asterionic width, which is approximately 99 mm. The occipital index (Martin's index 129) is approximately 72.0.

Viewed in profile, when the skull is orientated in the Frankfurt plane, the occipital region is seen to project far beyond a vertical line through the external auditory meatus, a feature seen in *Homo* but not in *Australopithecus*. The occipital condyles lie between the external auditory meati and the foramen magnum is elongate. The basi-occipital projection is short.

Table 1 Measurements of Olduvai H. 24 Cranium (in mm)

Glabella to inion cord	147.0
Glabella to bregma cord	88.5
Bregma to inion cord	78.5
Bimastoid crest breadth	122.0
External orbital angle width	107.0
Minimum frontal width	75.0
Foramen magnum length	28.5
Foramen magnum width	25.0
Length nasal bones	19.5
Nasion to prosthion	60.0
Nasion to orale	61.0
Nasion to left side of pyriform aperture	38.5
Nasion to naso-spinale	36.0
Naso-spinale to prosthion	25.0
Maximum breadth of pyriform aperture	25.0
Palatal width at alveolae of M^1	37.0

Table 2 Measurements of Teeth of Olduvai H. 24 (in mm)

Left side	Bucco-lingual breadth	Mesio-distal length
P^3	(12.0)	9.0
P^4	(12.5)	9.1
M^1	(13.0)	12.6
M^3	(14.5)	12.0

(4) The sphenoid bone. Nearly all the sphenoid is preserved including the pterygoid plates but not the pterygoid hamuli. In general appearance this bone is very similar to that seen in *Homo*, but this area requires detailed study in order to elucidate its significance taxonomically.

(5) The temporal bones. In the right temporal only the superior portion of the squamosal and part of the zygomatic process are missing. The mandibular fossa is perfectly preserved and is deep and narrow. The external auditory meatus is large and rather parallel-sided. The posterior part of the tympanic plate rises steeply to separate the meatus from the mastoid region. The tip of the mastoid process is broken off and the original size can only be estimated approximately from the preserved part. The zygomatic process is slenderly built and lacks the wide lateral shelf and outward flaring generally seen in *Australopithecus*.

The greater part of the left temporal bone is missing except for a small fragment in the medial region of the mandibular fossa.

(6) The face and palate. (*a*) The nasal bones. Both nasal bones are preserved with only the tips of the lateral processes on either side slightly damaged. The contact of the two bones in the midline is marked by a distinct keel which continues almost to the end of the nasal area. The margins of the pyriform aperture are not quite intact, but at its widest point it measures approximately 25 mm. The nasal length from nasion to the left lateral lip of the nasal aperture is 42.5 mm and nasion to nasospinale 36.0 mm. The nasal index (Martin's index 148) is 69.4, that is hyperchamaerrhine. There is a well developed anterior nasal spine at the centre of the pyriform aperture and from this point a very distinct keel runs downwards in the mid-line on the naso-alveolar clivus. (*b*) The zygomatic bones. The right zygomatic bone is reasonably well preserved; only the zygomatic process and a chip from the frontal process are missing. The root of the zygomatic arch lies approximately above a point between the first and second molars. The left zygomatic bone is missing. (*c*) The maxillae. The right maxilla is almost complete; parts of the alveolar process are missing, particularly in the region of M^2, and at the canine jugum the bone is also missing. The left maxillary bone is less complete, the zygomatic process, part of the nasal surface, and much of the posterior part of the alveolar process are missing. At the incisor sockets the alveolar margin seems to be preserved lingually but is broken labially. At present the margin runs straight across between the two canine alveoli and is not curved; but it is difficult to assess the original form on account of the damage. The whole of the median palatal suture is preserved. The right side of the bony palate has been displaced posteriorly by approximately 2 mm. The palate is seen to be reasonably deep (depth of alveolar processes at the first molars is approximately 15.0 mm). (*d*) The palatine bones. The palatine bones are intact and the areas of their contact with the maxillary tuberosities and with the sphenoid are well preserved.

(7) The teeth (see Table 2) present in the cranium as now reconstructed are as follows: (*a*) The crown of the left M^3. This is slightly broken on the distal aspect. The occlusal surface is undamaged and is very wrinkled with no sign of wear. (*b*) The left M^1 is intact and is firmly rooted in the maxilla. The enamel of the crown shows a degree of flat wear and the dentine is only exposed in a very small area on the protocone. (*c*) The left P^4 is complete. Its bucco-lingual width is less than that of M^1 and it is rather rectangular in form. (*d*) The left P^3 is partially preserved, the mesio-lingual area is broken away. (*e*) the right M^3 is partially preserved, the paracone and part of the protocone are broken away. The tooth compares closely with the intact left M^3. (*f*) The right M^2 is incomplete; it is broken diagonally so that the lingual and distal area is missing. (*g*) The right M^1 is nearly complete, only the protocone is missing. Its wear and structure are like those of the left first molar.

In addition to these teeth several fragments of molars and premolars were also recovered during sieving. It has not yet been possible to fit these fragments on to the cranium.

(8) Cranial capacity. It is not possible at this stage to give a close estimate of cranial capacity but preliminary determinations give a figure in the order of 560 cm^3.

(9) Endocranial region. Considerable parts of the endocranial morphology are preserved.

Comparisons with Other Hominids

There is still some evidence of distortion in the reconstruction. This has resulted in the vault of the skull being lower than it was originally and the backward projection of the occipital is now exaggerated.

The frontal bone does not exhibit the marked post-orbital constriction that is seen in the australopithecines from South and East Africa, nor does the supra-orbital element of the frontal bone curve backwards to the same extent. Seen in both lateral and vertical views the supra-orbital torus and glabellar region form a more or less straight line whereas in all known species of *Australopithecus* the glabella tends to project further forward with the lateral edges of the supra-orbital torus swinging backward. The parietal bones extend outwards from the sagittal suture with only a slight downward curve at first, and then bend steeply downwards to meet the squamosal parts of the temporal bones. The parietal region of the brain is thus more expanded than in *Australopithecus*, where the parietals usually begin to curve downwards close to the mid-line. Even allowing for the backward distortion of the occipital region this area of the skull extends further behind a vertical line through the external auditory meatus, when the cranium is in the Frankfurt plane, than in the australopithecines. The mandibular fossae are deep and very similar morphologically to those of *Homo sapiens* and wholly unlike those seen in *Australopithecus*. The nasal bones are long and slender with a marked keel in the mid-line.

The discovery of this skull, which is clearly a member of the genus *Homo* as defined in 1964[6], although it has certain primitive morphological features, raises an important issue. Although it is clearly not an australopithecine it nevertheless differs in certain important respects from the incomplete type of *Homo habilis* (Olduvai H. 7). Yet it resembles the paratype from Bed II (Olduvai H. 13) in both cranial and dental characters. At the same time, the dentition of the type of *Homo habilis* shows considerable resemblances to that of Olduvai H. 16, from lower Bed II, Maiko Gully, although differing in some respects. The problem therefore is whether or not there are two forms of *Homo* in Beds I and II or whether the differences between the two groups can be accounted for on the basis of individual variation and sexual dimorphism.

Although only part of the upper dentition is preserved in the cranium from DK, there are other specimens from Beds I and II which have a comparably small or even smaller tooth size and are morphologically similar. These clearly belong within the same group. They include a complete upper molar (Olduvai H. 6) from the site of *Australopithecus boisei* and an isolated molar (Olduvai H. 21), also probably from Bed I.

In Olduvai H. 24 from DK and in H. 13 from MNK certain important diagnostic characters of the skull are preserved, including the area of the temporal bones around the external auditory meatus and most of the occipital bones. These features, together with the morphology of the teeth, clearly indicate that both specimens belong within the genus *Homo*.

Although the occipital bone of the type specimen of *Homo habilis* (Olduvai H. 7) is not preserved it is evident from the structure of the parietal bones, and especially the form of the lambdoid suture, that the occipital bone must have been morphologically similar to that of *Homo erectus*, that is to say, the lambdoid suture is in the form of a low, wide arch and not V-shaped. This form is also seen in the skull of Olduvai H. 16 from lower Bed II. In contrast, the form of this suture in both Olduvai H. 24 from DK and Olduvai

H. 13 from MNK and, indeed, the whole form of the occipital bone, is very similar to that seen in *Homo sapiens* today: the line of the suture descends sharply from lambda in the form of an inverted V. There are thus two types of occipital morphology, one represented by Olduvai H. 24 and Olduvai H. 13 and the second by the type of *Homo habilis* and Olduvai H. 16.

The teeth of Olduvai H. 7 and H. 16 are megadont and within the size range of *Australopithecus africanus*; yet, in other respects, they display a number of morphological differences, especially in the premolars.

Distinct differences from the australopithecines are also evident in the cranial morphology, particularly in the parietals. Although the frontal bone of the type of *Homo habilis* is missing, a large part of this bone is preserved in Olduvai H. 16. Both the minimum frontal width and the width between the temporal crests is greater than in any known australopithecine.

Until the discovery of Olduvai H. 24 it was considered possible that the difference in morphology and in size between the cranial parts and dentition of the type of *Homo habilis* from Bed I and those of the paratype from Bed II (Olduvai H. 13) might have resulted from the elapse of a prolonged time interval. Because Olduvai H. 24 is chronologically near to the type of *Homo habilis* and yet more closely resembles the paratype from Bed II this explanation is no longer tenable. There remains the question of sexual dimorphism and it is possible that Olduvai H. 13 and H. 24 represent females of *Homo habilis* with the type and H. 16 representing the males. The difference in the morphology of the occipital region in the two groups, however, cannot be disregarded and suggests the possibility of taxonomic variation.

Beyond doubt, the new specimen represents the genus *Homo* as defined by Leakey, Tobias and Napier and differs fundamentally from the australopithecines. At the same time it is not entirely certain that it necessarily represents a female of *Homo habilis*.

We thank Dr A. Walker of the University of Nairobi for checking the text and measurements and for most valuable comments.

The behaviour of *X*-linked glucose-6-phosphate dehydrogenase locus in a mule and two hinnies provides support for Lyon's single active *X* hypothesis.

THERE have been several studies of *X* chromosome DNA replication and the behaviour of *X*-linked genes in the female mule[1-6] but the results are not in agreement on the frequency with which the two parental *X* chromosomes (X^D and X^H) show late DNA replication. Here we present additional data on the expression of the *X*-linked glucose-6-phosphate dehydrogenase (*Gd*, E.C.1.1.1.49) locus in a female mule and two female hinnies. (The hinny is the reciprocal cross *Equus caballus* ♂ × *E. asinus* ♀.) The mule and one hinny were less than one year old and the third animal was a 35 day old hinny foetus obtained by hysterotomy. All were bred at the Veterinary School and ARC Unit of Reproductive Physiology and Biochemistry, Cambridge, England.

Fibroblast cultures were established from the three animals by standard methods. The medium used was McCoy's 5a (modified) supplemented with 15% foetal calf serum (McFC15). Cloning of fibroblasts was carried out as follows[7]. Healthy exponentially growing fibroblast cultures were trypsinized, and the cell suspension was diluted as necessary to a final dilution of about thirty cells per ml. One drop of this suspension (0.03 ml.) was placed in each well of an appropriate number of Falcon Microtest II culture plates. (Each plate contains ninety-six wells of 0.5 ml. capacity. For each experiment five or six plates were seeded.) Then 0.2 ml. of McFC15 was added to each well and the plates were covered and incubated in a 100% humidity incubator in an atmosphere of 5% CO_2 in air. They were examined after 3 and 5 days and wells containing one colony were marked. The plating efficiency varied from 20–40%, which was similar to that obtained in conventional plating experiments using the same cell suspensions.

After 10–14 days, wells containing single colonies were trypsinized and the cell suspension transferred to 60 mm Falcon Petri dishes. When these dishes were confluent, the cells were either transferred to culture bottles to allow more extensive growth or, alternatively, the G6PD types were determined on the cells in the Petri dishes without further passage. Cells from each original culture and from a number of clones were stored at −70 or −196° C in a cryoprotective medium containing 15% glycerol. Lysates were prepared from both original cultures and clones by freezing and thawing in 0.015 M Tris-borate buffer (*p*H 7.8) containing 0.005 M EDTA, 0.02 g% 'Triton X-100', 2 mg% NADP and 0.05% (v/v) 2-mercaptoethanol. Electrophoresis ('Cellogel', Chemetron, Milan) was carried out for 1.25 h at 4° C at a potential gradient of 45 V/cm and the gels were stained for glucose-6-phosphate dehydrogenase[5].

+ Strong; ±, faint; −, absent; E, erythrocytes; F, fibroblasts.

Gd is seen as a single band in both parental species, Gd^H moving slower than the Gd^D (refs. 2 and 8). The faint slower bands seen in both parental species and the hybrids after starch gel electrophoresis represent breakdown products. The earlier samples from animals 100–196 were typed on starch as described earlier[2]. A number of other hybrid animals of both sexes as well as the parental species have been studied using both erythrocytes and fibroblasts without cloning. The *Gd* types are summarized in Table 1, and clearly confirm *X*-linkage of *Gd* in the Equidae. The parents of the three hybrids that were cloned are included in this table and show the expected *Gd* patterns. The interrelationship of the various hybrids which we have studied in detail is shown in Fig. 2. The hybrids, with one exception, develop a strong Gd^H band and either a faint or no Gd^D band. The exception (animal 192) has a stronger Gd^D band than Gd^H band. This inter-animal variation may explain the lack of agreement between different workers[3,4].

The *Gd* results obtained on 303 clones derived from three hybrids are given in Table 2. Two hundred and ninety-seven of these clones showed either the Gd^H or Gd^D band. Six clones were mixed (Gd^H/Gd^D), two of these were recloned, and 106 out of 107 of these sub-clones showed either Gd^H or Gd^D while one was again mixed (Table 3). In all animals, irrespective of the cross, the frequency of the two types is significantly different from 50% ($P > 0.0005$). This results from a deficiency of clones showing Gd^D.

Recloning the two mixed clones at a later passage showed that the proportion of Gd^D sub-clones (0.16) is significantly lower than expected, if it is assumed that these mixed clones originated from two cells, one Gd^D and one Gd^H. This suggests powerful selective forces acting *in vitro*.

A number of conclusions can be drawn from these results.

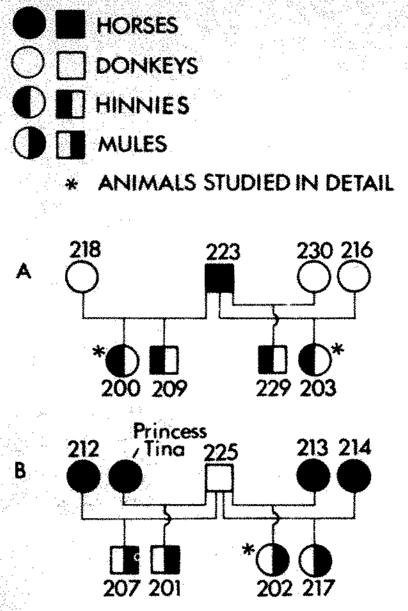

Fig. 1 Pedigree charts of the mules and hinnies studied. The numbers refer to numbers in Table 1. *A*, Hinnies; *b*, mules.

First, the mixed expression seen in the hybrids and some of the original cultures derived from them can be accounted for by the expression of one *X* chromosome only in any given cell and its descendants, as postulated by Lyon[9,10], and not from partial activity of both *X* chromosomes as postulated by Grüneberg[11] in his complemental *X* hypothesis. It could be argued, however, that the minor allele is expressed in less than 10% of the cells, in which case it would not be detected by the methods used here without sub-cloning. It seems unlikely that in a system where if the expression of an allele is equated to 100, all relative activities from 100 : 0 to 0 : 100 can reversibly occur for two alleles as suggested by Grüneberg[11], we would expect to find 81.7% of one type, 16.6% of the other and only 1.7% mixed, which are the results obtained here. Second, it can be concluded that active cell selection over a fairly short period of time occurs during *in vitro* fibroblast culture and that this selection would usually seem to be against those cells expressing Gd^D irrespective of whether the X^D is maternal or paternal in origin. This indicates that the maternal cytoplasm does not preferentially activate the maternal *X* chromosome or effect subsequent cell selection in these hybrids. Third, studies of *X*-linked loci using electrophoretic methods seem to demonstrate activity of a given locus only when it is expressed in more than 10% of the cell population. Original cultures from animals 202 and 203 both showed a minor fast band (Gd^D) at an early passage; this was subsequently lost during culture. In both these animals the frequency of Gd^D cells as demonstrated by the typing of clones was between 0.1 and 0.3 in different experiments. The original cultures from the foetus (200) never showed a fast Gd^D band; in spite of this, 9.0% of clones showed expression of Gd^D. These results are interesting in the light of the results reported by Sharman and his co-workers[12–14] on *X*-inactivation in marsupial hybrids in which they demonstrated preferential late replication of the paternal *X* chromosome and inactivation of the paternal *Gd* and phosphoglycerokinase (*PGK*) loci. Finally, the results obtained here agree with other data showing that the proportion of late replicating X^D ranged from 0.67–1.00 in six female mules and eight female hinnies[6]. If late replication of a given chromosome represents its genetic inactivation, then the autoradiographic results suggest that the proportion of cells expressing Gd^D should vary between 0.33 and zero which fits very closely to the results obtained here. Similar results have recently been reported for four mules by Cohen and Rattazzi[5].

Table 2 *Gd* Expression in Clones derived from Fibroblasts from Three Equine Hybrids

Animal No.	Expt.	No. Gd^D	No. Gd^DGd^H	Total	Proportion Gd^D
200	VIII	4	–	40	0.100
(Hinny ♀)

Cl	XIV	9	1	58	0.155
C8	XV	8	–	49	0.163
Total		17	1	107	0.159

These findings support the single active *X* hypothesis originally put forward by Lyon[9,10]. They demonstrate clearly activity of only one *Gd* allele in any given cell, which has also been shown for man[15,16]. Unfortunately, the other *X*-linked enzyme systems *PGK* and α-galactosidase which we have tested have failed as yet to show different mobilities in horse and donkey and so cannot be tested. Furthermore, these data demonstrate *in vitro* cell selection in favour of those cells carrying an active X^H. Examination of uncloned fibroblasts and erythrocytes from these animals also shows predominant expression of Gd^H (Table 1) suggesting that the proportion of cells with an active X^H *in vivo* are reflected in our *in vitro* results and that these are not therefore due to differential plating efficiencies of the two cell types. The one animal showing equal expression of the two types is unavailable for further study. Lyon[9,10] has postulated *in vivo* cell selection to account for variation in expression of sex linked loci in the mouse and man and the demonstration of such strong selective forces *in vitro* due to the activity or inactivity of a single *X* chromosome lends support to the hypothesis that similar selective forces may be acting *in vivo*. Finally, the close agreement between the autoradiographic data[2,4–6] and the genetic data presented here adds further support to the hypothesis that late replication is the cytological manifestation of genetic inactivity. A final proof of this would be provided by autoradiographic studies on the two clonal types derived here. These studies are at present in progress.

We thank Mrs G. Anderson, Mrs E. Cameron and Miss V. Niewczas-Late for technical assistance. This work was supported by a grant to J. L. H. from the Medical Research Council of Canada. Financial support from the Children's Hospital Research Foundation of Winnipeg is also gratefully acknowledged. W. R. A. is supported by the Thoroughbred Breeders Association. Collection of material from some of the animals in Portugal was supported by a grant to J. L. H. and R. V. S. from the Wellcome Trust. We thank Dr M. J. Freire and his veterinary colleagues for Portuguese samples.

Non-Random Late Replication of *X* Chromosomes in Mules and Hinnies

F. GIANNELLI

Paediatric Research Unit, Guy's Hospital Medical School, London SE1

J. L. HAMERTON

Department of Genetics, Children's Hospital, Winnipeg, and Departments of Paediatrics and Anatomy, University of Manitoba

Autoradiography of lymphocytes and fibroblasts has shed more light on the behaviour of *X* chromosomes in mules and hinnies.

THE process of DNA replication and genetic activity in *X* chromosomes of female mules and hinnies has been studied[1-6] without any agreement on the relative frequency with which the two parental *X* chromosomes (X^D and X^H) become late replicating and genetically inactive. Additional autoradiographic results on six female mules (*E. asinus* ♂ × *E. caballus* ♀) and eight female hinnies (*E. caballus* ♂ × *E. asinus* ♀) are presented here. One of the hinnies (No. 203) was bred in Cambridge[5], three of the mules (Nos. 27, 33, 100), subject of a preliminary communication[2], were obtained from various sources in Great Britain, while the remainder of the hybrids were from Portugal.

Lymphocyte and fibroblast cultures were established by standard methods[7,8]. Mixed lymphocyte cultures, using female donkey and horse blood were set up as controls, for the hybrid cultures. ^{3}H-Tdr (specific activity 5 Ci/mmol, Amersham) in a concentration 0.3–0.5 µCi/ml. was added to the leucocyte cultures 3–4 h before collection and colcemid was added 1.5 h before termination of the culture. Fibroblast cultures were labelled with 0.3 µCi/ml. 6 h before termination and colcemid was added 3 h later. Slides were prepared by air drying, stained lightly with lacto-acetic orcein and suitably spread metaphase plates were photographed. Autoradiographs were prepared by standard methods[2,9]. The cells which had previously been photographed were relocated and examined for a differentially labelled *X* chromosome. (This was defined as a medium sized chromosome which had at least twice as many autoradiographic grains as any other chromosome of similar size. This definition was adoped because the donkey has a submetacentric autosome much larger than the *X* and with a large heterochromatic paracentric region which is often densely labelled in late S.) The morphology of the differentially labelled *X* chromosome (*DLX*) was then determined by examination of the photographs taken before autoradiography. The two *X* chromosomes in the female hybrids are quite different, one (X^D) being submetacentric, while the other (X^H) is metacentric[1,2] (Fig. 1).

Twenty-one suitable metaphase plates from each of two hinnies and one mule (Nos. 100, 188, 203) were selected for quantitative autoradiographic studies, and karyotypes prepared. The total autoradiographic grains for each cell and for each of the five longest medium sized submetacentric and metacentric chromosomes were then counted. Grain counts were also made on samples of cells from the mixed leucocyte cultures, selected either at random or for the presence of a differentially labelled *X* chromosome.

The blood and skin cultures from the fourteen animals studied contained varying proportions of labelled cells and of cells with a differentially labelled *X* chromosome (Table 1). This did not influence the relative frequency of cells with a differentially labelled X^D or X^H. The relative frequencies differed significantly from 0.5 in every hybrid from which enough cells could be analysed and in each case there was an excess of DLX^D (Table 4). In the mixed leucocyte cultures, on the other hand, the number of horse cells which has a DLX was greater than the number of donkey cells with a DLX (Table 2).

The relative frequencies of DLX^D and DLX^H in cultures from individual mules or hinnies did not differ significantly from the overall frequencies for their own group (Tables 1 and 3). The hinnies behave in a similar fashion to the mules, but are possibly less homogeneous and seem to show a slightly higher frequency of DLX^H (Table 3).

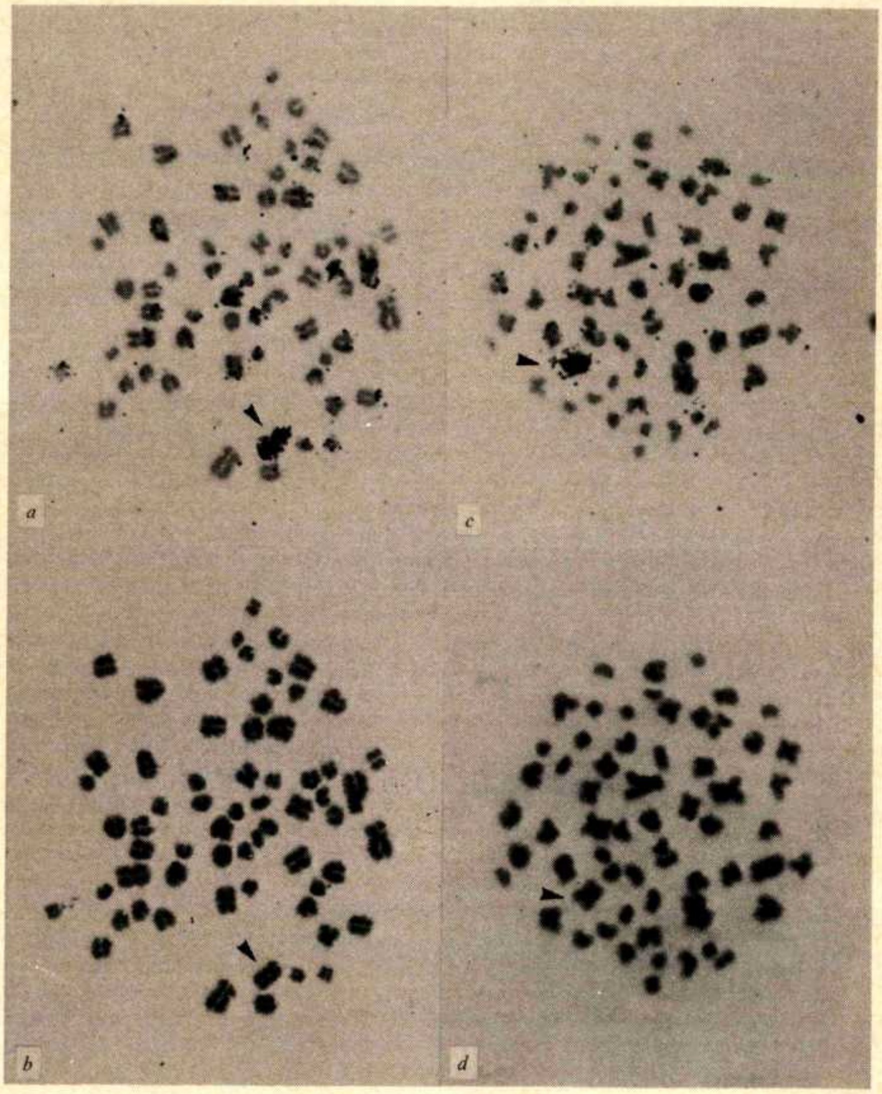

Fig. 1 Two metaphase plates from the same hybrid, the first showing (*a* and *b*) a submetacentric chromosome (arrowed) and the second (*c* and *d*) a metacentric chromosome (arrowed) differentially labelled. These chromosomes presumably represent, in order, the donkey and horse-derived X chromosomes.

In the sample of twenty cells selected at random from a mule and each of two hinnies (Table 4) the grain counts over the most densely labelled medium sized submetacentric and metacentric chromosomes showed the same regression line on the total cell grain counts, but the former chromosome had clearly higher grain counts than the latter. If these chromosomes are taken to represent respectively the X^D and X^H chromosome, these data seem to agree with the qualitative observation that the X^D chromosome is more frequently differentially labelled. Furthermore, the proportion of X chromosome grains counted over X^D seems to be very similar in the mule and the two hinnies.

Finally, in the mixed leucocyte cultures the regression of the grains counted over the differentially labelled X chromosomes, the most densely labelled X-like chromosomes, on the total cell grain counts was very similar in the horse and donkey cells. The covariance analysis (Table 5) showed that the grain counts over the X^H and X^D were very similar after allowance had been made for the labelling over the rest of the complement.

These results show that in both crosses irrespective of the direction of the cross, X^D is consistently more often differentially labelled than X^H. This differs from the findings of Mukherjee and his co-workers[1,3] but is in broad agreement with the observation of Cohen and Rattazzi[6].

Mukherjee and Sinha[1] used both longer labelling and colchicine times for blood cultures, while for skin cultures Mukherjee *et al.*[3] used a shorter labelling time than ours. Their results, however, differ in the same direction in both culture systems from those reported here; this suggests that the discrepancy cannot be explained by a variation in labelling procedure.

In the present study the DLX was defined as the chromosome of compatible morphology which had at least twice as many grains as any other chromosome of a similar size. This is in agreement with the illustration of Mukherjee and Sinha[1] who did not discuss their criteria in detail, but is less strict than that used in their later article[3] in which the DLX is defined as the chromosome with a grain count of at least 50% the total grain count over the whole complement.

In our opinion, this definition is too strict because of the difficulty of counting fifty grains or more over an *X*-like chromosome, which means that all cells with a total grain count of 100 or more over the remainder of the complement would have to be rejected. To see whether a more strict definition of *DLX* could affect the results presented here, however, all cells in which the grain counts over the *DLX* were not greatly in excess of twice that over any chromosome of similar size were rejected, leaving only those cells with a "very hot" *DLX* available for analysis. This procedure did not alter the ratio of DLX^H to DLX^D (Table 1). It seems reasonable to conclude from this that the way in which the *DLX* is defined is unlikely to account for the differences observed. Could any peculiarity or intrinsic difference in the labelling of X^D and X^H, not associated with the process of facultative heterochromatinization of the *X* chromosome, for example, a higher rate of DNA synthesis in X^D than in X^H at some stage of late S, be responsible for the difference which we have observed between the frequency of differentially labelled X^D and X^H in the hybrids' cultures ?

Data from the control cultures suggest that this is not so. The mixed lymphocyte cultures showed that the horse lymphocytes have a G_2 similar to that of the donkey and have a differentially labelled *X* chromosome at least as frequently. Admittedly a mixed lymphocyte culture is not a perfect control for cultures from hybrids in which each chromosome must be compared with the haploid sets from both parental species. But covariance analysis of grain counts over the *DLX* in the mixed lymphocyte cultures shows that, when account is taken of the labelling over the rest of the complement, DLX^D and DLX^H label in a similar fashion during the part of S studied This is confirmed by the similarity of the regression of grain counts over the presumptive X^D and X^H on total complement grain counts (TGC) in the three animals studied quantitatively (Table 4). Furthermore, an analysis of lymphocyte cultures from the hybrids shows that with an increase in labelling time the proportion of labelled cells increases and that of cells with a *DLX* decreases, while the relative frequency of DLX^D and DLX^H remains the same (Tables 1 and 6).

Finally, can these results be explained on the basis of an error in the identification of the X^D due to the presence o

morphologically similar late replicating autosome which mimics the behaviour of the DLX? Our definition of the DLX precludes this explanation unless the DLX^H had less than half the grains counted over this autosome much more often than the DLX^D. This could occur either if the DLX^H usually had lower grain counts than the DLX^D or if it was in the differentially labelled state less often. The data presented do not fit the first of these alternatives so that it seems reasonable to accept the second.

Table 2 Autoradiographic Data from Mixed Lymphocyte Cultures

Donkey	96	92	10	0.1086			

A further possibility which might account for our results is biased selection of cells or chromosome identification. To avoid this, the analysis of autoradiographs was conducted as independently as possible of the morphological chromosome analysis (a chromosome was classified as differentially labelled before analysis of the unlabelled photographs, and karyotypes were made by an individual who was unaware of the autoradiographic results). It is difficult, however, completely to exclude bias in an analysis of this type. The most serious cause of observer bias is the *a priori* expectations. In the study described here our intention was to investigate the relationship between differential labelling and genetic inactivity of one X chromosome, and it was expected that a 1:1 relationship would be found between the DLX^H and DLX^D in accordance with earlier findings[1]. Preliminary observations on differential labelling in cells with three mules[2] showed this was not so and it was considered a tentative hypothesis that the reciprocal cross might show the reverse, namely a greater frequency of DLX^H than DLX^D. On both counts therefore the results reported here are contrary to *a priori* expectations and lead to the conclusion that X^D is significantly more often differentially labelled than X^H in both mules and hinnies.

These results must now be considered in relation to the Lyon hypothesis (LH). In contrast to the suggestion of others[1,3] the mule may not provide a simple cytological test of random inactivation for reasons which have already been discussed[4]. These hybrids are, however, useful in studying the relationship between differential labelling of one X chromosome and genetic inactivation. Data on glucose-6-phosphate dehydrogenase (*Gd*)[5] show that the frequency with which Gd^D is expressed in fibroblast clones derived from three hybrids is in almost exact inverse proportion to the frequency with which X^D is observed to be differentially labelled in both lymphocytes and fibroblasts. Furthermore, qualitative data on expression of Gd^D show that, with the exception of one animal, it is expressed far more weakly than Gd^H in all the hybrids studied[10]. Cohen and Rattazzi[6] have reported a close correlation between the frequency of DLX^D and the expression of Gd^D in four further female mules. In each animal the X^D was more frequently late replicating and, correlated with this, Gd^D was the minor component. Hook and Brustman[10] have studied *Gd* expression in organs from 37 female mules. They found that in most tissues (blood, pancreas, brain, cervical cord, kidney and parotid gland) Gd^H is preferentially expressed. In thyroid and lung there appeared to be random expression while in the liver Gd^D seemed to be preferentially expressed.

The excellent correlation observed in our studies and those and Rattazzi[6] between differential labelling and the expression of an X-linked locus implies a definite relationship between these two phenomena; proof of such a relationship will be provided by autoradiographic studies on the clones discussed in the previous article[5]. These are in progress. A comparison of X chromosome behaviour and *Gd* expression in both the mule and the hinny suggests that neither the maternal cytoplasm nor the maternal environment is important in determining which X chromosome becomes genetically inactive and differentially labelled in the female hybrids or in determining which cell type proliferates preferentially

The significant excess of cells with an inactive and differentially labelled X^D is most easily explained by a difference between the two X chromosomes either in respect to the mechanism of "induction" of facultative heterochromatin or to the increased fitness which an active X^H confers on the hybrid cells resulting in selection in their favour. There are at least two alternatives which might account for a difference between X^D and X^H in regard to the mechanism of heterochromatinization; first, that X^D is simply more prone to become heterochromatic, or, second, that heterochromatinization commences earlier in the donkey than in the horse and that this is retained in the hybrids and so leads to an earlier involvement of X^D compared with X^H. The studies reported in the previous article[5] on fibroblast clones suggest *in vitro* cell selection in

favour of cells with an active X^H; studies by Hook and Brustman[10] suggest that *in vivo* cell selection occurs in different organs.

Our finding of one animal (No. 192)[5] with a preponderance of Gd^D, on which unfortunately autoradiographic studies were not possible, suggests that there may be inter-animal variation in the expression of *Gd*. Inter-animal variation could perhaps account also for the discrepancy between our autoradiographic results and those of Mukherjee and his colleagues[1,3].

Table 5 Comparison by Covariance Analysis of the Grain Counts over Differentially Labelled X Chromosomes (A) or the Most Densely Labelled X-like Chromosomes (B) in Horse–Donkey Mixed Blood Cultures

Adjusted mean	$\bar{Y}'_1=29.55$	$\bar{Y}'_2=28.17$	$\bar{Y}'_1=22.90$	$\bar{Y}'_2=22.70$
Difference	$\bar{Y}'_1-\bar{Y}'_2=1.38$		$\bar{Y}'_1-\bar{Y}'_2=0.20$	
s.e. of difference	1.88		2.55	
Probability	$0.5>P>0.4$		$0.95>P>0.90$	

Scatter diagrams were made before these analyses. These have shown a linear relationship between the presumptive X chromosome grain counts and the counts over the rest of the complement. The variance of Y was fairly constant over the range of total grain counts used and this was similar in the two samples compared. The regression coefficients of the individual samples used in this comparison were significantly different from zero, but did not differ significantly from each other.

Our data and those of Cohen and Rattazzi[6], however, clearly show that X^D tends to be more often heterochromatic than X^H in the tissues of female horse–donkey hybrids which have been available for study.

We thank Drs R. V. Short, W. R. Allen and M. J. Freire, with his colleagues in Portugal, for samples of material. Collection of Portuguese samples was supported by grants to J. L. H. from the Wellcome Trust. During this work J. L. H. and F. G. were supported by the Spastics Society. J. L. H. also acknowledges support from ARC and the Canadian Medical Research Council. We also thank Mrs F. F. Collins, Mrs J. Hallett, Miss A. Fryer, Miss V. M. McGuire and Mr L. Grixti for technical assistance.

Table 6 Analysis of the Tendency for the Proportion of DLX^D to Vary according to the Proportion of Labelled Cells in Blood Cultures of Mules and Hinnies

Type of hybrid	Regression coefficient	SS due to regression	χ^2	P
Mules	−0.5341	352.4	0.429	>0.5
Hinnies	−1.033	1,531	1.86	>0.1
All*	−1.189	3,777	4.6	<0.05

This analysis was conducted using the angular transformation method[11].

* Since the proportion of DLX^D in the hinnies is lower than that of mules and their cell samples contribute chiefly to the class with a relatively high proportion of labelled cells the data regarding both types of hybrid together are not very meaningful.

Ivory Coast Microtektites: Fission Track Age and Geomagnetic Reversals

IN this article we report our measurements of the age of Ivory Coast microtektites, and discuss the association of microtektites with geomagnetic reversals. Microtektites are small glassy particles (<1 mm) found in sediment cores from the oceans adjacent to the Australasian and Ivory Coast tektite fields[1]. They resemble tektites in outward form and composition. Comparatively few microtektites have been recovered so far, but Cassidy *et al.*[2] believe that the total mass of Australasian microtektites may be at least 10^{10} kg, which is 10^5 times larger than the estimated mass of the tektites.

Our Ivory Coast microtektites were kindly given to us by Dr B. P. Glass, and we have used the fission track method of dating[3]. In this method the known rate of spontaneous fission of ^{238}U (we have used a fission decay constant of 8.42×10^{-17} yr^{-1}) allows the age of the material to be determined after the uranium content of the material has been found by exposing the material to a known dose of thermal neutrons. Then the age in years of the sample, A, is given by[4]

$$A = (\rho_n/\rho_i)\ 5.01 \times 10^{-8}\ F \qquad (1)$$

where ρ_n and ρ_i are the natural and induced etch pits per unit area, and F is the time-integrated flux of neutrons (usually a few times 10^{15} thermal neutrons cm^{-2}).

To count as many natural fission tracks as possible in our limited sample, each microtektite was mounted individually in epoxy resin on a plastic backing, and polished to uncover successive layers for etching and examination under the microscope. The etchant was hydrofluoric acid (40% by volume) used for 30 s at 21° C. The initial diameters of the microtektites were ~150–400 μm, and each etching and polishing (using 0–1 μm diamond powder on a microcloth) removed a layer about 20 μm thick. The last few layers were usually saved for irradiation by thermal neutrons, and the same counting procedure was used for the irradiated samples.

Fig. 1 shows typical photomicrographs of natural and induced etch pits, and a poorly polished section including several spurious etch pits is shown for comparison. Altogether 26 microtektites were examined, some in greater detail than

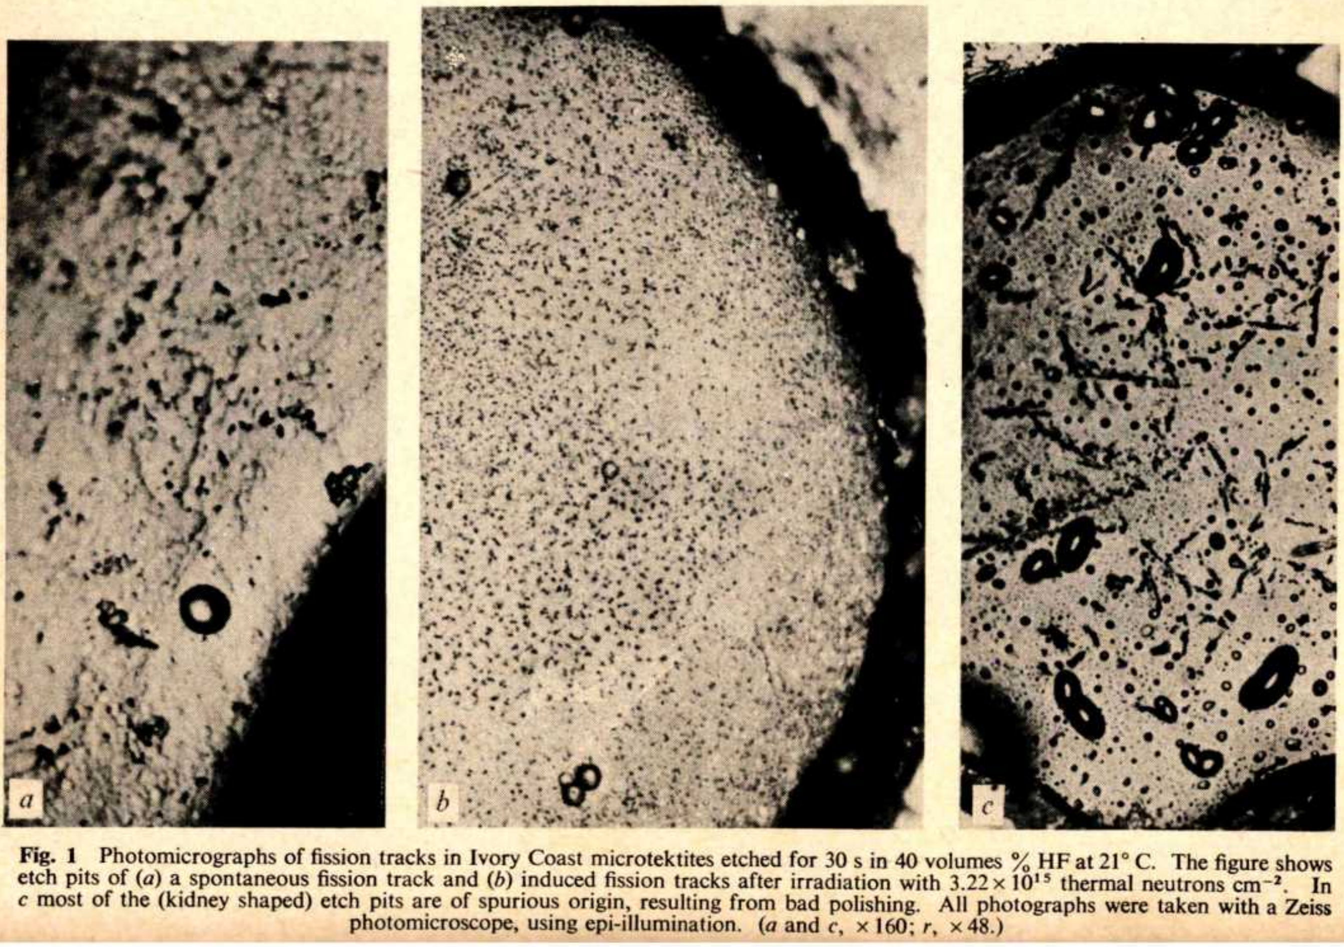

Fig. 1 Photomicrographs of fission tracks in Ivory Coast microtektites etched for 30 s in 40 volumes % HF at 21° C. The figure shows etch pits of (*a*) a spontaneous fission track and (*b*) induced fission tracks after irradiation with 3.22×10^{15} thermal neutrons cm^{-2}. In *c* most of the (kidney shaped) etch pits are of spurious origin, resulting from bad polishing. All photographs were taken with a Zeiss photomicroscope, using epi-illumination. (*a* and *c*, ×160; *r*, ×48.)

‡ Based on twenty-six microtektites from core K9–56. Of the eighteen microtektites which could be successfully analysed (yielding fifty-seven natural tracks), thirteen were irradiated in a reactor for age and U content determinations.

§ Glass[7].

¶ Determined by us. The Ivory Coast tektite age is based on only one specimen (from Ouellé) kindly given to one of us (S. A. D.) by Professor F. Kraut, director, Museum of Natural History, Paris. A total of 1,073 natural tracks was observed over an area of 2.65 cm^2.

others; 57 natural tracks were found (in 18 microtektites) over an area of 40.89 mm^2, and 3,627 induced tracks over an area of 8.40 mm^2.

Table 1 summarizes our results and those of Gentner *et al.*[5], based on the fission track method to date tektites and microtektites from the Australasian and Ivory Coast strewn fields. K–Ar ages of the tektites are also shown, but microtektites are too small for this method. Our ages for the Ivory Coast tektites and microtektites agree among themselves, although they are somewhat lower than those reported by other workers (except for the deposition age[7] of ~0.8 to 1.0 m.y. for the microtektites). The errors shown in Table 1 for our fission track ages are made up of statistical (Poisson) errors, uncertainties in the neutron dose (±5%) and, for the microtektite measurements, uncertainties in the uranium content of the samples which could not be irradiated.

It has already been pointed out that the Australasian microtektites occur within a zone ≈30–50 cm thick associated in time with the last geomagnetic reversal[2,5,8]. In other words, the Australasian microtektites appear to coincide in age with the boundary between the present normal epoch (Brunhes) and the preceding reversed geomagnetic epoch (Matuyama), which is believed to have occurred about 0.7 m.y. ago according to magnetic measurements of lavas and deep-sea sediments[9–11]. There have been four geomagnetic epochs of alternating polarity over the past 3.6 m.y., each lasting ~10^6 yr, interspersed with shorter events (<0.2 m.y.) when the polarity was briefly antiparallel to that of the epoch. We believe that it may be possible to associate the Ivory Coast microtektites with the last such event (Jaramillo) which occurred about 0.9 m.y. ago[12,13]. Ivory Coast microtektites have been found so far in two cores, V19–297 (2° 37′ N lat., 12° 00′ W long.) and K9–56 (3° 23′ N lat., 15° 37′ W long.). The microtektites in V19–297 are concentrated[5] in a thin layer about 15 cm thick that occurs about 40 cm below the Matuyama–Brunhes boundary. The Jaramillo event has been lost in this core, but palaeontological stratigraphy suggests[14] that it coincides with the fall of the microtektites. Our microtektites come from the K9–56 core, and our age of 0.88±0.13 m.y. (as well as the weighted mean of our measurements and those of Gentner *et al.*, 0.94±0.10 m.y.) is in close agreement with the estimates of the age of the Jaramillo event, which range from 0.85 to 0.97 m.y. Unlike the stratigraphic determinations of age in deep-sea sediments (whether palaeomagnetic or palaeontological) which may have been affected by bottom currents and mud-burrowing organisms the fission track determinations are absolute. The age of the Ivory Coast tektite found by us, 0.86±0.06 m.y., is also in good agreement with the date of the Jaramillo event.

Glass and co-workers[2,8] have already suggested that the phenomenon responsible for the Australasian field may also have caused the Matuyama–Brunhes reversal, and similar arguments can be put forward to account for the Jaramillo event. These hypotheses of course do not say whether the mass of microtektites and tektites came from outside the Earth, or whether a comet or meteorite struck the Earth and scooped out material which then fell back to the Earth as a spray of tektites and microtektites. But it seems plausible from what is known of the cause of the geomagnetic field, and its instability, that such comparatively small disturbances could reverse the field direction.

In this context we wish to suggest a possible explanation of the sudden changes in marine fauna which seem to be associated with geomagnetic reversals. Some marine microorganisms become extinct, and others suddenly appear, in sediments at reversal levels[15]. If tektites are produced by cometary impacts, as Urey has suggested, then the gases such as frozen ammonia and methane contained in cometary nuclei might have appreciable ecological effects when rapidly introduced into the atmosphere and oceans. Some organisms thrive on methane, for example, while others do not; ammonia, which would dissolve rapidly in sea water, would have similar effects. Large explosions of methane–air mixtures, sparked by atmospheric lightning, may also have occurred. There needs to be a quantitative examination of whether cometary impact could cause reversals and produce faunal changes over large areas of the globe.

The cometary hypothesis also avoids the difficulties which have appeared in the lunar-origin hypothesis of tektites and microtektites now that lunar samples are available. Although minute glassy particles that look like microtektites have been found on the Moon[16,17], the chemical compositions are not similar[18]. The resemblance of the exceptional lunar sample 12013 (ref. 17) with two untypical Java tektites[18,19] is not firm evidence of affinity.

Finally, we wish to describe in more detail some of the precautions taken in our age measurements of the Ivory Coast microtektites. In determining the age of a material by the fission track method it is important to ensure that no thermal effect that would lower the measured age has occurred in nature. Heating results in the fading of tracks and in shrinkage of the etch-pit diameters of the surviving tracks[20,21]; it can be corrected for by comparing the diameters of the etch pits for natural and freshly induced tracks. These correction factors are obtained by a series of isothermal annealing experiments, and Fig. 2 shows a comparison of the natural and induced fission etch-pit diameters of Ivory Coast microtektites. The *t* test shows no significant difference; so the observed age may be regarded as the true age. The same applies to the Ivory Coast tektite (natural diameter: 4.65±1.24 µm; induced diameter: 4.67±1.09 µm).

The uranium content in p.p.m. by weight is given by

$$C = 9.445 \times 10^7 \rho_i/(D.R_{ap}\cos^2\theta_c.g.f(t).F) \qquad (2)$$

where D is the density of the material (g cm^{-3}), R_{ap} is the apparent range of an average fission fragment, θ_c is known as the critical angle of etching, g is a geometrical factor and $f(t)$ the prolonged etching factor for the material (our unpublished work). $D.R_{ap}$ is taken to be the same as found for a reference glass (U-2) with a known amount of uranium (that is, 2.41 g cm^{-3} × 7.6 µm), and $g=1$ (for 4 π geometry, the contribution of fission fragments from both sides of each etched surface being taken into account). ρ_2 and F are as in equation (1).

The critical angle[3] is defined as the minimum track inclination with the surface that leads to successful etching. We have determined this angle for microtektites using a novel comparison method. A ^{252}Cf spontaneous-fission source was used to bombard first an indochinite and then a microtektite for equal lengths of time under identical ("2π") geometry. The tektite and the microtektite were then etched in identical conditions (30 s at 21° C in 40 volumes % HF). The number of fission-fragment etch pits per unit area can be shown to be in the ratio $(1-\sin\theta_{c,1})/(1-\sin\theta_{c,2})$, where the subscripts 1 and 2 refer to the two materials being compared. The critical angle for the microtektite is found to be 24° 13′, which is in good agreement with that for the indochinite (that is, 25° 21′, determined in a similar manner by comparison with a glass slide of known critical angle). The error in each case is ±30′. This agreement in itself is a confirmation of the chemical similarity of tektites and microtektites. (The critical angle for the soda–lime glass slide, in contrast, is 35° 30′.)

The prolonged etching factor $f(t)$ results from the fact that, as the etching process progresses and new surfaces are revealed, fresh fission tracks are continually encountered and developed. This growth in numbers is not compensated by a corresponding obliteration of tracks which had begun to be developed earlier and whose actual end-points may have been reached in the meantime, for they continue to yield recognizable, although progressively shallower (less acute) etch pits. The function $f(t)$ is defined as the ratio ρ_t/ρ_0, where ρ_t is the track density observed on etching the sample for time t, and ρ_0 is the value for zero etching-time (the density of "etchable tracks" in any surface), obtained by extrapolating the experimental growth curve backwards to $t=0$. Neglecting the factor $f(t)$ in equation (2) would result in an overestimate of the true value of uranium content (whereas in the case of age determination this factor cancels out if both the natural and the irradiated samples are etched in identical conditions).

Fig. 3 shows the growth of observed etch-pit densities with the duration of etching for an irradiated microtektite, an indochinite, and the (soda–lime) reference glass U-2 (all etched in 40 volumes % HF at 21° C—$f(t)$ is temperature-dependent). The value of $f(t)$ for the microtektite is found to be 1.16 for an etching time $t=30$ s. Again, the fact that the growth curves for microtektites and tektites are nearly parallel (whereas that for soda–lime glass is much steeper) demonstrates their kinship.

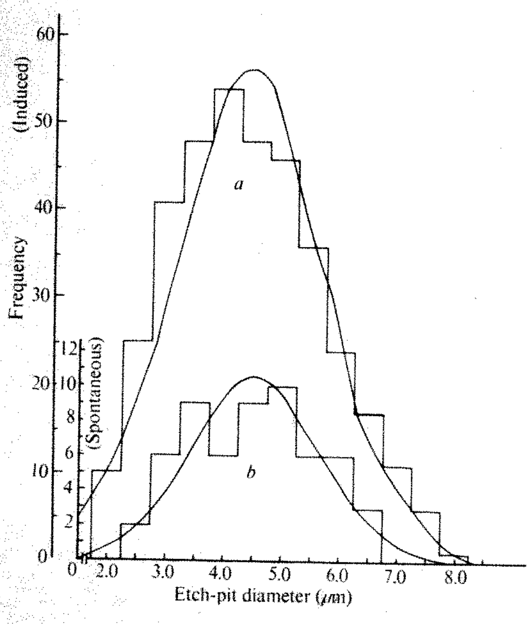

Fig. 2 Comparison of the etch-pit diameters of spontaneous and induced fission tracks in Ivory Coast microtektites etched for 30 s in 40 volumes % HF at 21° C. In the case of elliptical pits, the major axis has been taken instead of the diameter. A Gaussian has been fitted to each histogram. The absence of a significant difference between the two distributions indicates that no thermal lowering of age has occurred in the natural microtektites. *a*, Induced fission (4.41±1.30) μm, 367 tracks; *b*, spontaneous fission (4.52±1.09) μm, 57 tracks.

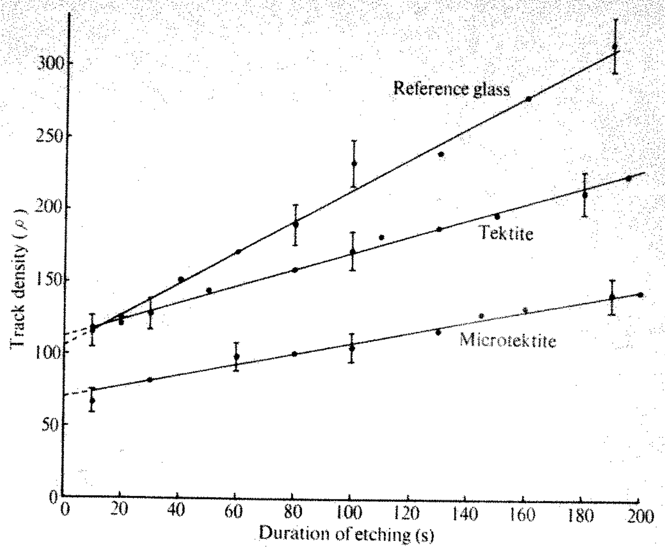

Fig. 3 Prolonged etching factor $f(t)$. The diagram shows the cumulative growth in the number of fission tracks (observed over an arbitrarily chosen area of 0.15 mm^2 in each case) as a function of the duration of etching. Irradiated sections of a microtektite, a tektite and (soda–lime) reference glass have been etched in identical conditions (30 s in 40 volumes % HF at 21° C). The value of $f(t)$ is defined as the ratio of the track density ρ at time t to that at time $t=0$ (see text for discussion); it is found to be 1.16 for the microtektite, 1.15 for the tektite, and 1.41 for reference glass (at $t=30$ s in the etching conditions used). The representative error bars shown indicate (Poisson) standard deviations of actual numbers observed.

The mean value of uranium content, based on thirteen irradiated microtektites, is found to be 0.43 p.p.m. by weight (corresponding to 0.81×10^4 tracks cm^{-2} induced by a fluence of 1×10^{15} neutrons cm^{-2}), with a range of 0.37 to 0.51 p.p.m. between individual samples. This may be compared with an average of 0.23 p.p.m. (and a range of 0.12 to 0.48 p.p.m.) calculated from the results of Gentner *et al.*[5]. Incidentally, our determination of the Ivory Coast tektite uranium content, that is, 1.3 p.p.m., compares well with the value reported by Rybach and Adams[22], namely, 1.10 p.p.m. (mean of twenty samples).

In conclusion, the fact that the ages of the Ivory Coast and Australasian microtektites and tektites seem to coincide with the dates of the last two geomagnetic reversals raises the important question of a causal relationship. If a cometary impact with the Earth resulted in the production of tektites and microtektites, and in the reversal of the geomagnetic field, an interesting corollary is the possible effect of the released gases on the ecological balance on land and sea areas.

Measurements of the Gegenschein from Space

THE zodiacal light, which is produced by light scattered from small interplanetary particles, gradually declines in brightness with increasing angle of elongation, ε, from the Sun. As the anti-solar point (ε = 180°) is approached, the surface brightness again increases slightly to produce the counter-glow or gegenschein. This diffuse feature can be best observed against the sky background when it lies outside the region of the Milky Way. Fig. 1 depicts the sky background brightness at the anti-solar point as a function of time throughout the year. The integrated light from stars predominates during the two Milky Way traverses. Observations of the gegenschein are made best away from the Milky Way in February, March and April, or in August, September and October.

Ground-based observations are weakened by atmospheric extinction and diluted by the upper atmosphere airglow and light scattered in the Earth's lower atmosphere. Measurements of the gegenschein from above the Earth's atmosphere avoid the difficulties of these atmospheric effects. Accordingly, an experiment was designed for the wheel of an orbiting solar observatory (OSO–6) to measure the brightness and polarization of the sky. The photometer–polarimeter, which was built by Ball Brothers Research Corporation includes a Sun-shielded objective, a collimator, quartz rotators, a quarter-wave plate, a double-cut prism, interference filters and a field lens, all bringing the light beam through a 2° diameter field stop to an EMR 641 E-type photomultiplier. Although the instrument was designed to measure polarization, we are concerned here only with photometric data at 5000 Å. The equipment is operable only during satellite daytime and scattered light enters the photometer when the Sun (or the sunlit Earth) is at an elongation 90° or less with respect to the line of sight. The gegenschein region, however, is free of photometric contamination from this effect.

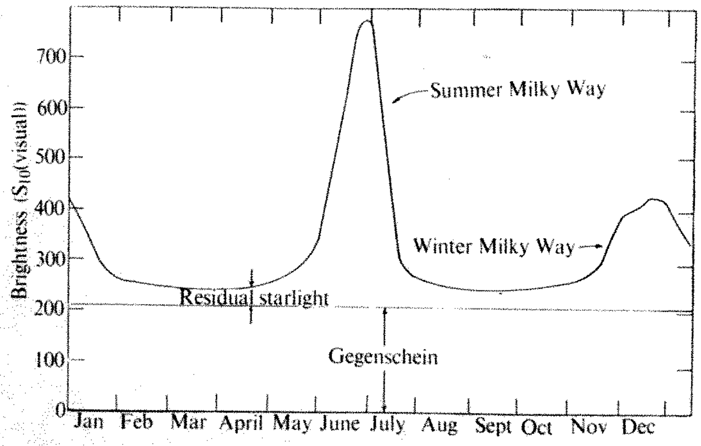

Fig. 1 Sky brightness at the anti-solar point as a function of time as it would appear to an observer above the Earth's atmosphere. Ordinates give surface brightness in units of tenth magnitude stars per square degree, S_{10} (visual). The contributions of the gegenschein are assumed constant, but the starlight (plus galactic light) contributions exhibit maxima during Milky Way traverses.

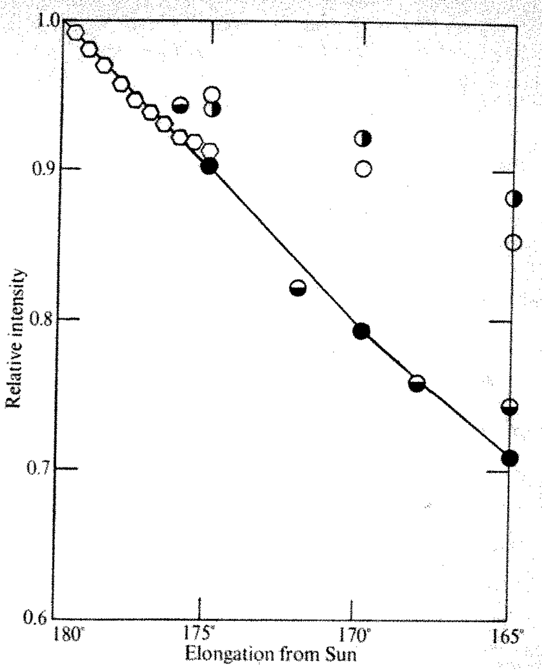

Fig. 2 Relative intensity distribution in the gegenschein. Comparison of the brightness distribution of the gegenschein as measured by ground observers with OSO-6 measurements (●) at 5000 Å. ○, ref. 2; ○, ref. 4; ◑, ref. 3; ◒, ref. 1.

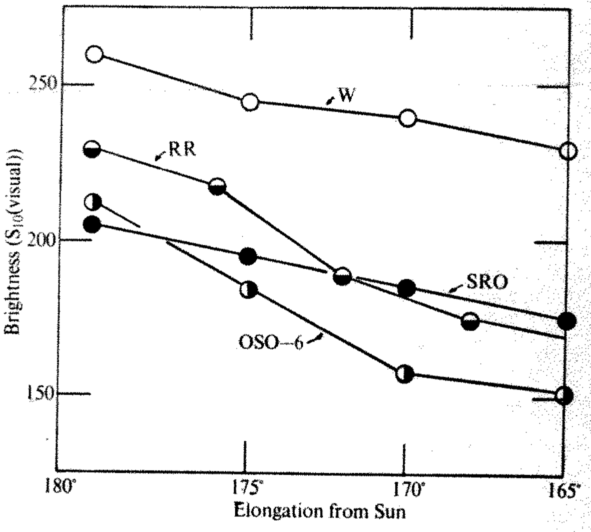

Fig. 3 Absolute gegenschein brightness comparison of the absolute surface brightness in the gegenschein from OSO-6 observations and ground-based observers (W: ref. 3; RR: ref. 1; SRO: ref. 4). Preliminary calibration of the space observations.

Comparison of measurements made towards the same point in the celestial sphere at two different points in the orbit, plus comparison of the space-based and ground-based observations of the Milky Way, indicate that the instrument is operating well and yielding trustworthy information.

In Fig. 2 we compare the relative brightness of space measurements of the gegenschein within 15° of the anti-Sun position with some corresponding ground-based results. The present space measurements are in accord with the data of Roach and Rees[1] and the recent studies of Roosen[2] in suggesting a fairly steep photometric gradient from the anti-Sun position. Weinberg[3] and Smith, Roach and Owen[4] find a less steep gradient. Fig. 3 shows a comparison of the absolute brightness of the gegenschein as measured from space in comparison with several published ground-based observations. The space observations are based on a preliminary absolute calibration.

As further material becomes available we hope to extend the discussion to ±25° from the anti-solar position and improve the absolute calibration. Also, the photometry will be extended to other colours (4000 Å and 6100 Å) and the polarization data evaluated. The exact variation of the polarization at elongations between 150° and 180° is of special interest in assessing the nature of the scattering particles.

We thank R. Wilson, H. Zimmerman, and Wm. Dagle of Ball Brothers Research Corporation for the assembly of the polarimeter–photometer. This work was supported by a NASA grant to Rutgers University.

Martian Blue Haze Clearings and Flash Phenomena

THE relative lack of contrast in the blue ($\lambda < 0.44$ μm) in examinations of the surface markings of Mars has long been known, but occasionally and unpredictably, detailed blue structure can be seen briefly during blue haze clearings. There is some controversy about these phenomena[1,2], although in our opinion they are well established. A blue obscuring haze may be attributed to scattering of light by suspended particles[3–7] of diameter less than 0.4 μm, in the martian atmosphere so that blue haze clearings would result whenever meteorological conditions caused a partial precipitation of particles, but the mechanisms for the removal remain as obscure. We propose a simple meteorological mechanism which is consistent with available data from martian oppositions and flash observations..

There is evidence[8] of significant water on Mars. Although the occurrence of liquid water would be a transitory, nonequilibrium possibility, Shorn[8] speculates that the triple point pressure may be exceeded occasionally. Fine martian atmospheric dust is assumed to influence the haze. Essentially, our clearing mechanism is the removal of available atmospheric dust by the condensation of water vapour on dust nuclei during highest humidity, resulting in precipitation, clearing the air[9,10].

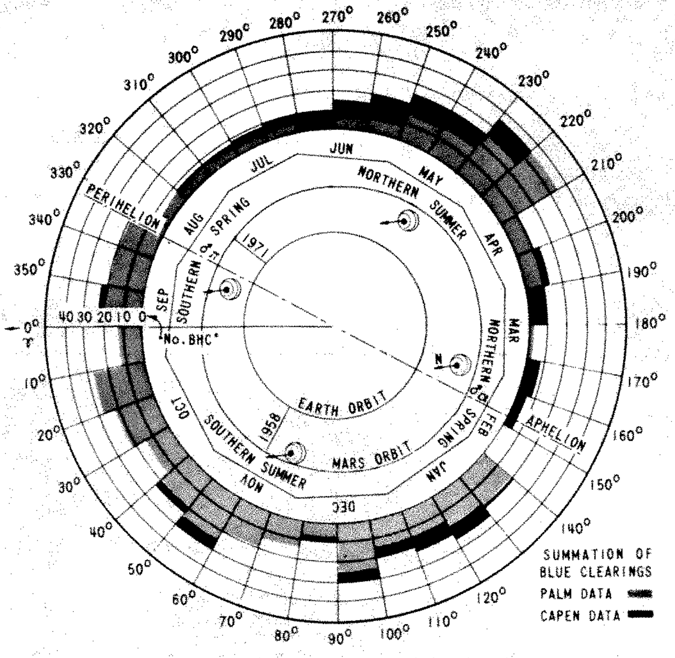

Fig. 1 Histogram chart of martian blue haze clearings (BHC), plotted against martian heliocentric longitude. All seasons shown are martian but months are terrestrial. *The scale shows the number of BHC per 10° sector. The Palm data are opposition data; Capen data are general data for the period October 1966 through March 1968. Earth months correlate with opposition (Palm) data. Arrows on Mars indicate approximate North Pole orientation. It must be kept in mind that this histogram is, in part, a function of the positions of the terminal points of the interval over which one averages in presenting the discrete histogram representation of what is really a smooth curve.

Spectra of water vapour on Mars during 1968–69, taken as Mars was rapidly approaching the Earth[8], show a shift of the martian H_2O lines relative to the telluric water vapour signature and show much more water on Mars than had recently been found[11,12]. Humidity can exceed 50% over large areas, which is conducive to occasional precipitation on martian aerosols and changes the atmospheric conditions radically, explaining even abrupt blue haze clearings. Possibly fogs settle on Mars, and rain and snow may originate from reported, heavier, grey and yellow clouds[10].

Consider the orbits of Mars and Earth as being fixed in space (Fig. 1). All months referenced are Earth months. The orbital perihelion of Mars lies in the August sector and the aphelion in the February sector. Mars may, of course, be anywhere in its orbit during August or February, but Earth's near circular orbit provides for closest oppositions around August or September, as for 1971. At close oppositions, Mars is in its northern hemisphere autumn. For oppositions during February and March, Mars is in the middle of the northern hemisphere spring. These are important considerations because most of the data on both blue haze clearings and flares[13] have been taken during oppositions.

With one polar cap partially or completely dissipated during either martian summer, the humidity will then be highest and conducive to possible precipitation. Blue haze clearings (opposition data) have predominated during martian summers, (both northern and southern) which are favourable seasons for precipitation.

Earth weather probably prejudiced blue haze data, influencing the deficiency during February and March as shown in Fig. 1. Conversely in northern skies it is best to look at Mars when the cool air contributes to greater clarity even at larger distance.

For an April opposition, Mars is not far from its northern summer solstice, favouring increased precipitation in its northern hemisphere, but if this is indeed a factor it implies that opposition blue haze clearings in March and February should be more frequent than are indicated. Another effect, however, is the occurrence of aphelion in the late February sector implying a colder planet overall, with lower humidity due to increased condensation of volatiles. Further correlations of locations of clearings with seasons are indicated.

During our summer months of June, July and August the monthly integrated averages from opposition data[14] of blue haze clearings have been almost a constant. Capen's data[15], however, show a progressive decrease for this period. This total number (approximately 100) has also been low. Most of these data were obtained during oppositions when the warming martian southern hemisphere was emerging from winter, thermal gradients were increasing, with winds carrying dust. The humidity may still be too low for significant precipitation, producing regional atmospheric hazes while northern terrestrial weather hinders observations.

From September to February, the average opposition blue haze clearings per unit time initially increases and is then approximately constant.

The centre of the season of more frequent blue clearings lags the martian southern solstice by about three terrestrial weeks. The duration of this clearing season, however, is almost triple that of the season which centres 3 weeks after the northern summer solstice. This, too, is explicable by increased temperatures over more martian surfaces. This follows from the fact that in the vicinity of northern summer solstice the polar axis inclination favours higher polar surface temperatures, but is thermally opposed by being in the orbital aphelion, whereas in the vicinity of southern summer solstice, polar inclination and orbital eccentricity coordinate to produce higher temperatures, possible precipitation and clearings. Furthermore, while the line of solstices is near to the line of apsides it misses coincidence with it by a few months, causing a long warm period even though the southern summer is shortest. Solar power to Mars is over 40% greater at perihelion than at aphelion because a longer season of more frequent clearings in the austral summer part of the martian orbit is anticipated and supported by the available data (Fig. 1). Apparently orbital eccentricity has greater influence than the inclination of the polar axis.

Recent observations[15] show that, excepting early February, blue clearings have occurred throughout the year. Since Mars presents its smallest image to astronomers during February, atmospheric blurring could easily mask detail. Although a blue deficiency of Mars was observed from Earth during NASA Mariners 6 and 7, none was detected in photographs from the fly-bys with red, blue, and green filters[16]. This indicates a terrestrial, faint image, or space contained effect. The high contrast and definition of the Mariner images at close range may have made any obscuration undetectable. Qualitative martian colour contrasts could hardly be established from these unprecedented series of photographs. Opik[6] feels that Leighton's conclusion of non-existence of the blue haze based on Mariner photographs (which show limb haze) is not justified[10]. Blue light photographs taken at Flagstaff, Arizona and Bloemfontein, South Africa, with equivalent refractors, Kodak film and developers consistently show more blue details in the Flagstaff photographs[10]. Flashes of light have been reported on Mars[16,17] which could, it seems, be possible ground water since no volcanic activity is known.

With possible precipitation on Mars, a new perspective is gained in the Mars blue haze clearings and known soil erosion. White and blue clouds, possibly composed of water, have long been seen which are conducive to rapid atmospheric clearing. Evidence indicates that Earth's summer haze, with appropriate martian conditions could possibly block much blue light from all, or part, of Mars.

There are four factors involved; the inclination of the martian axis of rotation, the eccentricity and orientation of the martian line of apsides, the occurrence of precipitation and dust and terrestrial seeing conditions. These can be combined to explain the distribution of reported opposition blue haze clearings. Photographs or vidicon observations from an orbiting (or lunar based) telescope, or stratoscope, could test our hypothesis by viewing Mars simultaneously from Earth and Earth orbit at times when the surface was obscured in the blue from the ground. Similar tests would be made early in a February when no clearings have been reported. These observations should show how terrestrial weather influences blue haze clearings.

We also speculate that numerous light flashes reported on Mars, coinciding primarily with the respective summer hemispheres at the times of observation, may be reflexions from temporary surface waters formed by precipitation.

Permeabilities of Precambrian Onverwacht Cherts and Other Low Permeability Rocks

QUANTITATIVE estimates of rock permeability are of importance in any branch of science or engineering where flow of fluids through rocks is considered. Although there is a large amount of data available for rocks with relatively high permeabilities (exceeding 1 mdarcy), very few data are available for rocks such as shales, cherts, dense carbonates and evaporites which may have permeabilities of less than 1 mdarcy. Permeability measurements on Precambrian cherts help to interpret the results of organic geochemical studies made on these ancient rocks.

The search for geological evidence about the origin and evolution of life on Earth has led to detailed searches for morphological and molecular fossils in Early Precambrian sedimentary rocks, most of which have extremely low permeabilities[1,2]. The oldest rocks considered so far are the Onverwacht Group of the Swaziland Sequence exposed in the Eastern Transvaal of South Africa. The age of this group is at least 3.2×10^9 yr. Fossil-like microstructures as well as polymeric organic matter (commonly called kerogen) have been found in carbonaceous cherts of the Onverwacht Group[3], but the biogenic nature of the microstructures is uncertain[4]. The presence of several kinds of molecular fossils in these rocks (*n*-alkanes, isoprenoid hydrocarbons, fatty acids, porphyrins, amino-acids) has also been reported[5–7]. But the significance of these microstructures and molecular fossils for the origin and evolution of life on Earth is still in question.

Nagy[8] has recently determined the permeability and porosity of a single sample of Onverwacht chert to be 5.7×10^{-7} mdarcy and 0.5% respectively. He showed that even at this low permeability there is the possibility of contamination of these rocks with organic compounds dissolved in fluids which have flowed through for several thousand million years. This finding has wide implications for the significance of organic compounds found in small concentrations in low permeability rocks of all geological ages.

In January 1968 we began to develop a novel liquid permeameter for measuring very low permeabilities in rocks. Permeabilities and porosities of four samples of chert from four different formations of the Onverwacht Group were measured. For comparison the same measurements were made on a sample of Precambrian Keewatin chert from Canada, a sample of Precambrian Bitter Springs limestone from Australia, and samples of Castile gypsum, Rustler dolomite, and Bone Springs limestone from west Texas.

Permeabilities were determined by a new technique described in detail elsewhere (S. K. Sanyal, R. M. Pirnie, III, G. O. Chen, and S. S. Marsden, jun., to be published). The sample is held in a Hassler sleeve which can be maintained at confining pressures as high as 10,000 pounds inch^{-2} with a hydraulic pump. Upstream pressures are maintained by a "thermal pump" which utilizes the thermal expansion of a liquid to create pressures $\leqslant 1{,}000$ pounds inch^{-2}. Pressures are measured with a low displacement, diaphragm-type transducer and permeabilities deduced indirectly from the pressure decline over a period of time.

For the permeability measurements reported here, hydraulic oil was used in both the hydraulic and thermal pumps by contrast with Nagy's choice[8]—a 2,000 p.p.m. NaCl brine. Theoretically permeability of a rock is independent of the flowing fluid but in practice this independence is not strictly valid[9]. Extremely low permeability rocks such as those studied have a higher permeability to air than to water[10]. This difference may be due to dehydration of minerals in contact with flowing air (causing an increase in permeability), or the swelling of clay minerals in contact with flowing water which would cause a decrease in permeability. The second effect can be minimized by use of strong brine or a non-interacting fluid such as hydraulic oil.

Permeability measurements were made at confining pressures between 1,500 and 1,800 pounds inch^{-2}. An increase in confining pressure on a rock generally reduces its permeability[9,11,12] and this effect is particularly evident for rocks of very low permeability[13]. Nagy[8] did not specify the confining pressures used and this to some extent limits a comparison of the results. Permeabilities were measured at various orientations to bedding because in the presence of small scale structures (laminations, banding, fractures, solution channels and so on), rock permeability depends strongly on the directions in which the fluid flows.

Porosity, φ, of a sample was calculated from its bulk volume, V_B, its dry weight, W_0, and its weight after it was saturated with oil under vacuum, W_s, by the relation

$$\varphi = \frac{W_s - W_0}{\rho_0 V_B}$$

where ρ_0 is the density of the oil.

Permeability and porosity values of the samples studied as well as directions of permeability measurements and confining pressures are listed in Table 1. For Onverwacht cherts, permeabilities vary from a value which is too small to be measured by our technique (that is less than 10^{-6} mdarcy) to 2.09×10^{-2} mdarcy, and porosities vary from 0.03 to 0.72%. The chert sample from the Hooggenoeg Formation had a very low permeability which probably approaches the value obtained by Nagy[8] (5.7×10^{-7} mdarcy). The other Onverwacht chert samples had permeabilities greater by several orders of magnitude. The Keewatin chert from Canada had a permeability of 1.1×10^{-4} mdarcy which is similar to the chert permeability given by Davis[14] (1.9×10^{-4} mdarcy). Permeabilities to air of two Precambrian cherts have been obtained by Smith *et al.*[15]; Gunflint chert from Canada had air permeabilities of 1.9×10^{-1} and 2.0×10^{-2} mdarcy and porosities of 0.44 and 0.55%, and Bitter Springs chert had values of 2.2×10^{-1} and 1.7×10^{-1} mdarcy and 0.62 and 1.15%. Thomas *et al.*[10] have shown that air permeabilities are generally slightly higher than liquid permeabilities in tight rocks. Therefore Gunflint and Bitter Springs cherts seem to be about as permeable as the most permeable Onverwacht cherts. Bitter Springs limestone, with a liquid permeability of 4.0×10^{-2} mdarcy and a porosity of 0.24%, is about as permeable and porous as samples of chert from the same formation.

With one exception, too few measurements were obtained to determine whether there was any relationship between perme-

Table 1 Permeability and Porosity Measurements

Sample No.	Name	Age	Porosity (%)	Permeability (mdarcy)	Direction of permeability	Confining pressure (pound inch^{-2})
Onverwacht cherts						
5–6	Theespruit Formation	Precambrian	0.72	2.09×10^{-2}	Perpendicular to laminations	1,500
5–10	Hooggenoeg Formation	Precambrian	0.03	$< 10^{-6}$	No specific orientation	1,700
5–18	Kromberg Formation	Precambrian	0.12	1.16×10^{-3}	Parallel to laminations	1,600

abilities and direction of flow within the rocks. Castile gypsum had permeabilities two to three orders of magnitude higher parallel to the laminations than perpendicular to the laminations. Three out of four samples of Onverwacht chert had measured permeabilities much higher than the single value reported by Nagy[8]. The relationship between measured permeabilities and true permeabilities during geological time is not known but cementation, compaction and metamorphism may have caused significant permeability reduction during the geological past. On the other hand, earth movements may have increased the effective *in situ* permeabilities of these rocks by inducing fracturing which may not be evident in small laboratory samples.

It is quite likely that fluids have been able to flow through these rocks by means of both intergranular and fracture channels. Our data suggest that flow of fluids in these rocks may have been even higher than estimated by Nagy[8], and consequently many of the Onverwacht cherts may have been host rocks rather than source rocks for some of the organic compounds they now contain.

Conversion of Oleic Acid to Saturated Fatty Acids in Severn Estuary Sediments

THE upper, biologically active, layers of Recent aquatic sediments contain considerable quantities of saturated and unsaturated long chain fatty acids[1-3], presumably from the living and dead organisms found there[4,5]. Although fatty acids are major constituents of organisms, in the upper layers of sediments, their concentration is of the same order of magnitude as that of sterols[6,7], usually minor constituents of organisms. The ratio of fatty acids to total organic carbon in marine sediment is at least ten times lower than in plankton[1], again indicating that fatty acids are subject to rapid changes in the sediment. Palmitic acid ($C_{16:0}$) is the most abundant saturated fatty acid in organisms, and oleic acid ($C_{18:1}$) the most widely distributed and plentiful of all fatty acids[4,5]. The lower, biologically less active, layers of sediments, contain little or no unsaturated fatty acid; palmitic acid is the most abundant of the fatty acids[1,2,8]. This difference between the upper and lower layers is unlikely to be the consequence simply of hydrogenation of the carbon–carbon double bands, for in this case the proportion of stearic acid ($C_{18:0}$) in the lower layers and the concentrations of saturated fatty acids would be larger. These reactions could occur by chemical and/or biological means, perhaps through the large number of anaerobes present in upper layers of sediments[9,10].

Our studies were designed to discover the fate of oleic acid in an aquatic sediment. The basis of our experiments was to add 9,10-^{3}H, 1-^{14}C-oleic acid to the upper layers of the Recent sediments of the Severn Estuary and then to isolate the labelled products of short term diagenesis. The ratios of ^{3}H to ^{14}C measured for the various saturated fatty acids obtained are compared with the $^{3}H/^{14}C$ ratio for the original oleic acid. We hope to extend the methods described here to other substances of geochemical and environmental chemical interest.

If oleic acid present in sediments is converted into saturated acids (of chain length C_{12} and above), two biochemical pathways could be operative: (1) the simple hydrogenation of unsaturated carbon–carbon bonds, followed by loss of C_2 units to give the fatty acids of shorter chain length (the degradative pathway); (2) total breakdown of oleic acid by β-oxidation to give C_2 units (probably as acetyl-CoA) followed by a resynthesis through the fatty acid synthetase complex[11] (the resynthesis pathway).

If the oleic acid introduced is labelled in the carboxylic carbon with ^{14}C and in the 9 or 10 positions with ^{3}H (to give 9,10-^{3}H, 1-^{14}C-oleic acid), the isotopic labels will be incorporated differently into the products of the two pathways outlined here.

In the case of the degradative pathway, which involves the simple loss of C_2 units without total breakdown, the ^{14}C will be lost from the molecule (for all acids except stearic), whereas all the ^{3}H will be retained. Thus, for fatty acids of length C_{16} down to C_{10}, the ratio of ^{3}H to ^{14}C becomes infinitely large, whereas for stearic acid the ratio stays the same as that of the added oleic acid. The ^{14}C removed from the long chain acids will appear in acetyl-CoA (as 1-^{14}C-acetyl-CoA), which will have a ratio of ^{3}H to ^{14}C of 0 to 1.

In the case of the resynthesis pathway, the various enzymatic reactions undergone during β-oxidation and resynthesis from the resulting acetyl-CoA will lead to loss of ^{3}H relative to ^{14}C. The first turn of the β-oxidation spiral will remove all the ^{14}C from the molecule as 1-^{14}C-acetyl-CoA. All the ^{3}H from C-9 will be lost (as $NAD^{3}H$ or $FAD^{3}H$) as this carbon becomes the terminal carboxylic carbon. The fate of the ^{3}H on C-10 may depend on the stereospecificity of the enzymes involved in the reduction step. Enzymes from various sources[12] have been shown to react stereospecifically with fatty acids and it is likely that the β-oxidation enzymes behave similarly, but their stereospecificity is unknown and either all or none of the ^{3}H could be lost from C-10 of the degraded fatty acid. The acetyl-CoA produced through the β-oxidation spiral could therefore contain anything between zero and 0.5 of the amount of the ^{3}H originally present in the oleic acid (all as 2-^{3}H-acetyl-CoA), and all of the ^{14}C. This acetyl-CoA is most likely to be incorporated into long chain fatty acids by the fatty acid synthetase complex which is present in many organisms, including *Escherichia coli* and yeast[11]. All the acetyl-CoA units to be utilized, except one, are first converted to malonyl-CoA before incorporation into the growing fatty acid. The overall effect is to lose approximately 0.67 of the ^{3}H present as 2-^{3}H-acetyl-CoA but to retain all the ^{14}C. In the case of palmitic acid, the overall result should be a ratio of ^{3}H to ^{14}C of 8.34 : 1, based on acetyl-CoA having an

100 μCi of 9,10-^{3}H-oleic acid and between 2.5 and 10 μCi of 1-^{14}C-oleic acid were injected into the sediment in each experiment. All the results have been normalized to an initial ratio of ^{3}H to ^{14}C for oleic acid of 20 : 1 (100 μCi of ^{3}H). The conditions of extraction and purification of the acids, and the corrections for losses in these procedures, are described in the text. The conditions of incubation were as follows: *A*, laboratory core, incubated for 6 days at 18–20° C; *B*, laboratory core, incubated for 9 days at 18–20° C; *C*, incubated *in situ* for 7 days, August 1970. *D*, incubated *in situ* for 17 days, September–October 1970; *E*, incubated *in situ* for 38 days, September–October 1970. The statistical errors in the ^{3}H values caused by variation in count rates were in all cases less than ±1%. The ^{14}C values will be subject to larger errors because of the lower count rates, and where the quoted yields are less than 10^{-10} Ci the error may be greater than ±5%.

initial ratio of ^{3}H to ^{14}C of 20 to 1. Experimental verification of this expected ratio comes from the work of Wakil[13] with the synthetase complex from avian liver, and other studies[14] in rat adipose tissue. Overall, the resynthesis pathway, starting from oleic acid with a ratio of ^{3}H to ^{14}C of 20 to 1 should generate palmitic acid with a ratio of ^{3}H to ^{14}C between 0 to 1 and 4.17 to 1, the exact value depending on the ^{3}H loss during β-oxidation. The theoretical ratios for lauric, myristic and palmitic acids formed via the resynthesis pathway are very similar.

Thus the two pathways, degradative and resynthetic, should give end products with very different ratios of ^{3}H to ^{14}C. Except for stearic acid, the degradative pathway causes a total loss of ^{14}C, whereas the resynthesis pathway causes an almost total loss of ^{3}H relative to ^{14}C. We are following only the flow of label and not the total flow of material through each pathway. From the actual ratios of ^{3}H to ^{14}C observed in the saturated fatty acids extracted from the sediments injected with labelled oleic acid, it is possible to calculate what proportion of the label has come through the degradative pathway compared with that arising by resynthesis.

Incubations of oleic acid in aquatic sediments were carried out either *in situ* in the mud of the Severn Estuary (National Grid Reference ST534832) at a depth of 10 cm below the surface, or in cores (15 × 3 cm) which had been removed from areas adjacent to the *in situ* sites, and then transferred to the laboratory. The area of study was chosen near the high water mark on a large expanse of mud flats. A thin layer of grey silt covered a 20 cm layer of black thixotropic mud which contained sulphide and elemental sulphur. The sites were covered by the tide for approximately 4 h in each 24 h, and the temperature varied between 5° and 25° C; the laboratory cores were incubated at 18°–20° C. Labelled oleic acid (from the Radiochemical Centre, Amersham, Buckinghamshire) was prepared by mixing aliquots of 1-^{14}C and 9,10-^{3}H-oleic acid (no additional unlabelled acid was added) to give a ratio of ^{3}H to ^{14}C of between 10 to 1 and 40 to 1. The resulting oleic acid (up to 100 μCi of ^{3}H) was injected (as a 'Tween 80' suspension) so as to cause as little disturbance of the sediment as possible. This represents the addition of a maximum of 0.2 μmol of free oleic acid.

After incubation for up to 38 days, the cores were removed and extracted for free fatty acids using a modification of the Dole extraction procedure[15], or with a 3 to 1 mixture of toluene/methanol. Carrier fatty acids were added (3 μmol for each acid) and the extract methylated with BF_3/methanol[16]. The methyl esters of the saturated acids were then separated from other material by preparative thin-layer chromatography on silver nitrate-impregnated silica gel[17], and finally separated into individual esters by preparative gas chromatography. The peaks corresponding to the even chain length saturated acids were collected directly in 10 ml. aliquots of toluene scintillator (NE 220: Nuclear Enterprises Ltd, Edinburgh) and the samples assayed for radioactivity using a Nuclear Chicago mark I liquid scintillation spectrometer. Quench corrections were applied[18].

Control experiments have shown that the isolation procedures used (Dole extraction, methylation, thin-layer chromatography) result in approximately 70% recovery of U-^{14}C-palmitic acid before preparative gas–liquid chromatographic analysis. Toluene–methanol extraction is less efficient giving 25% recovery of label before gas–liquid chromatography. Similar recoveries have been obtained for 9,10-^{3}H-oleic acid. Table 1 shows the amounts of radioactivity (in nCi) in the saturated fatty acid fraction estimated as being present in sediments after various periods of incubation with 9,10-^{3}H, 1-^{14}C-oleic acid. The figures listed are estimates calculated using these measured efficiencies of recovery of the saturated fatty acids.

The most striking feature of Table 1 is the low conversion of oleic acid into saturated fatty acids observed for all the incubations. The combined long chain saturated fatty acid fraction extracted from the mud was never found to contain more than 3% of the label from the added oleic acid, even though the labelled oleic acid rapidly disappeared (for example in experiment *B* of Table 1, only 5% remained after 9 days incubation). Thus, most of the label of the starting oleic acid does not appear in the free saturated fatty acid component of the mud. The usual fate of oleic acid added to this particular sediment is probably breakdown to acetyl units, which may then be oxidized to CO_2 and H_2O or incorporated into other compounds such as the carbohydrate constituents of cell walls.

Table 2 shows the ratios obtained after various incubation times, with 9,10-^{3}H, 1-^{14}C-oleic acid. There is a definite trend in the ^{3}H to ^{14}C ratio, which increases with decreasing chain length. We have already stated that acids produced by the degradative pathway would have a ratio of ^{3}H to ^{14}C of infinity, whereas those formed by the resynthesis pathway would have ratios of ^{3}H to ^{14}C between 0 to 1 and 4.2 to 1, starting with that for oleic acid—20 to 1. A combination of the pathways would give intermediate ratios. A qualitative

Table 2 Ratios of ^{3}H to ^{14}C measured in Saturated Fatty Acids from Severn Estuary Sediments after Injection of 9,10-^{3}H, 1-^{14}C-Oleic Acid

Acid	*A*	*B*	*C*	*D*	*E*
Stearic	29 : 1	24 : 1	30 : 1	21 : 1	38 : 1
Palmitic	44 : 1	23 : 1	34 : 1	66 : 1	29 : 1
Myristic	112 : 1	41 : 1	54 : 1	170 : 1	215 : 1 *
Lauric	440 : 1 *	—	142 : 1 *	627 : 1 *	

Procedures for incubation and isolation of the acids are given in the text. The ratios of ^{3}H to ^{14}C used in the injected oleic acid varied between 10 to 1 and 40 to 1; all the results have been normalized to a starting ratio for oleic acid of 20 to 1. The conditions of incubation (*A–E*) are given beneath Table 1.

* These values are subject to errors of greater than ±5%.

picture can be readily inferred from the data in Table 2. Lauric acid and myristic acid, which have high ratios of ^3H to ^{14}C, seem to arise chiefly through the degradative pathway, while palmitic acid, which has a ratio nearer that of oleic acid, seems to be formed through both pathways. The position with stearic is more complex, as a ratio of ^3H to ^{14}C greater than that of oleic acid is impossible according to the scheme outlined above. Some of the stearic acid, however, may be formed through a recycling pathway involving palmitic acid:

$$\text{oleic acid} \rightarrow \text{stearic acid} \rightleftharpoons \text{palmitic acid}$$

A ratio of ^3H to ^{14}C greater than that of oleic acid would then be obtained. Such recycling of metabolites is well known in biochemistry[13,19], and it is quite likely that recycling is also occurring here.

Table 3 Calculated Fractions of Labelled Saturated Fatty Acids derived by the Degradative Pathway

Acid	*A*	*B*	*C*	*D*	*E*
Palmitic	0.67 (0.69)	0.48 (0.53)	0.60 (0.63)	0.76 (0.77)	0.56 (0.60)
Myristic	0.84 (0.85)	0.65 (0.66)	0.72 (0.73)	0.90	0.92
Lauric	0.96	—	0.88	0.97	

The observed ratios of ^3H to ^{14}C used to calculate these results are taken from Table 2, and the conditions of incubation (*A*–*E*) are given in the footnote to Table 1. The values in this table have been calculated using the formula

$$x = \frac{c_{res}t_{obs} - c_{obs}t_{res}}{c_{obs}\,(t_{deg} - t_{res}) + t_{obs}(c_{res} - c_{deg})}$$

where x is the fraction of acid formed through the degradative pathway. t_{res} to c_{res} is the theoretical ratio of ^3H to ^{14}C obtained for an acid formed through the resynthesis pathway. t_{deg} to c_{deg} is the theoretical ratio ^3H to ^{14}C through the degradative pathway. t_{obs} to c_{obs} is the observed ratio of ^3H to ^{14}C in the purified methyl esters of the long chain fatty acids. The first figure of each value is that assuming minimal loss of ^3H through the resynthesis pathway; that in parentheses is assuming total loss of ^3H. Where only one figure is given, the two results differ by less than 0.01. Stearic acid has been omitted from this table because recycling between stearic and palmitic acids cannot be estimated.

The results in Table 3 provide an approximate order for the proportion of individual labelled saturated fatty acids formed from labelled oleic acid by the degradative pathway:

$$\text{lauric} > \text{myristic} \gg \text{palmitic}$$

A significant portion of the labelled palmitic acid is formed on the resynthesis pathway, which is probably a reflexion of the fact that the fatty acid synthetases of many organisms produce predominantly palmitic acid[12]. Thus shorter chain acids (lauric and myristic acids) formed through the resynthesis pathway would have been produced by partial degradation of palmitic acid, with concomitant dilution of label by the cellular pool of palmitic acid.

Several assumptions have been made in this treatment of the results, and these will be discussed briefly. It has been assumed that the major pathways for the transition of label from oleic acid to the saturated acids involve either removal of a small number of C_2 units by means of β-oxidation (degradative pathway), or total breakdown to acetyl-CoA followed by resynthesis (resynthesis pathway). These are the principal pathways of fatty acid metabolism in most organisms[20], and we have assumed that other pathways, such as α-oxidation[21,22], are of little importance. Our calculations of the proportions of flow of label through the two pathways also require the assumption that any acid which has been formed by the resynthesis pathway is not then subsequently totally broken down again. If this occurs, our estimates of the flow through the resynthesis pathway will be too low, for the label will be lost from the system. During the whole incubation period the ratio of ^3H to ^{14}C for oleic acid should remain constant, and any variation will cause errors in the calculations of the fractions of labelled acids derived by the two pathways. The oleic acid fractions recovered after the incubations had ratios of ^3H to ^{14}C within 10% of the starting ratios.

The composition and abundance of biolipids and geolipids present in Recent sediments vary markedly with depth. Measurement of these differences provides one approach to the problem of studying the path of carbon during diagenesis. Farrington and Quinn[23] measured fatty acids at various depths in Recent sediment from Narragansett Bay, Rhode Island. They concluded that $C_{16:0}$ is the predominant acid at the depths studied (surface to 52 cm) and that the concentrations of the unsaturated fatty acids $C_{16:1}$ and $C_{18:1}$ decrease more rapidly with depth than do the saturated fatty acids. Brogden[24] has studied the anaerobic decomposition of zooplankton in a mixture of sediment and seawater which had been sterilized and inoculated with bacteria from marine sediments. The quantities of $C_{16:1}$ and $C_{18:1}$ acids fell rapidly over the period of the experiment, whereas the concentration of saturated fatty acids increased. Brogden suggested hydrogenation of the unsaturated fatty acids.

The novel approach described here involves direct introduction of radiolabelled biolipids into a Recent sediment. It provides specific and detailed information on the fate of a labelled compound introduced into the sediment. The method involves only minor disturbance of the ecosystem and allows estimates to be made of the fluxes through various biochemical pathways. This work substantiates the current view[1,23] that oleic acid rapidly disappears after burial in a Recent aquatic sediment. We have shown that some of the atoms of oleic acid reappear in the saturated normal fatty acid fraction, although the conversion is small. It is probable that most of the oleic acid is metabolized by degradation of the carbon skeleton through β-oxidation to acetyl-CoA, followed by conversion to CO_2 and H_2O or incorporation into non-lipid cellular components. We have calculated the proportions of the various saturated acids which have been produced from labelled oleic acid by the pathways we have considered, namely the degradative and resynthesis pathways (Table 3). The majority of the label was incorporated through the degradative pathway with retention of part or all of the original carbon skeleton of the oleic acid. The proportion is highest for lauric and myristic acids. But there are difficulties in deriving detailed inferences from information of this sort. The two pathways must differ markedly in their capability for dilution of label. Thus, the degradative pathway is unlikely to be subject to a large dilution of label and the radioactivity incorporated can be used to estimate the rate of carbon flow in this pathway. In contrast, in the resynthesis pathway the label passes through the acetyl-CoA pool of the cell. Acetyl-CoA is a key metabolite in most cells, and several pathways lead into and away from this pool. Calculations using the flow of label through the resynthesis pathway probably underestimate the total carbon flow from acetyl-CoA to long-chain fatty acids.

Our experiments certainly show that oleic acid present in a Recent sediment can be converted into saturated fatty acids with retention of carbon skeleton over a period of a few days. The process is almost certainly effected microbiologically. Whether this represents a process which contributes significantly to the content of the saturated fatty acid fraction found in Ancient sediments is uncertain. The rapid loss of oleic acid during the short periods of our experiments, coupled with the slight incorporation into saturated fatty acids through both pathways, suggests, however, that the saturated fatty acids found in compacted Recent and Ancient sediments are not derived directly from the fatty acids originally contributed to surface layers, but are derived from a number of precursors through many metabolic pathways.

On occasions the steady process of sedimentation may be interrupted by the sudden deposition of large quantities of sediment as a result of major floods or earthquakes, and in this case the sediment might be buried complete with a greater abundance of biolipids and their immediate products of alteration. Another mechanism whereby fatty acids might escape direct biological alteration could be encapsulation within a seed or nut[25]. Our prime concern in this study has been to investigate the processes of hydrogenation which are believed to occur early in the formation of a sediment. In deeper layers, as lithification proceeds, free water is gradually removed and bacterial activity ceases. As the temperature and pressure rise, slow maturation processes begin. Hydrogen transfer is a part of these slow maturation processes. Thus radiolabelled cholesterol, when intimately mixed with a sample of pulverized Green River shale (Eocene) and heated in a sealed tube at 200° for 1,000 h, afforded various radiolabelled products which included 5α and 5β-cholestane (unpublished results). The relationships between biolipids incorporated into a freshly forming sediment and those geolipids remaining after the initial period of biological and chemical diagenesis probably now encompass the following: (1) complete retention of structure as in the odd-numbered alkanes originating in the surface waxes of plant debris; (2) partial retention of structure, as in the saturated fatty acids formed by the degradative pathway in the present study, and partial or complete retention of stereochemistry as in isoprenoid acids derived, presumably, from phytol[26]; (3) complete breakdown and resynthesis as in the saturated fatty acids formed by the resynthesis pathway.

This study indicates that hydrogenation processes play a part in the early diagenesis of fatty acids. We are investigating the fate of several unsaturated biolipids for which saturated geolipid analogues are encountered in Ancient sediments. It seems likely that saturated geolipids may have a dual origin—biologically effected hydrogenation during early diagenesis, and thermally and catalytically induced hydrogen transfer processes during maturation. These hydrogenation processes are the only ones tenable unless biological sources can be found for fully saturated geolipids such as steranes, triterpanes and tetraterpanes and related compounds[27,28].

We thank Drs G. Ware, R. Denton, V. Collins, L. Morris and B. Nicholls and Mr F. J. H. Mackereth for advice, equipment and facilities. We thank Mrs Pat Muir for collecting samples and for the microbiological studies and Mr D. Morgan and Miss J. Hay for technical assistance. We thank the SRC, NERC and NASA for financial support. P. J. E. is a Beit Memorial research fellow.

Late Quaternary Stratigraphy and Radiocarbon Chronology of Water Level Fluctuations in Lake Keilambete, Victoria

WHEN compared with the northern hemisphere, the southern hemisphere has provided little palaeoclimatic information on the past 30,000 yr. A systematic study of lakes is under way to help establish a reliable palaeoclimatic sequence covering this period in south-east Australia and to explore possible correlations with worldwide climatically controlled events. This is a preliminary report of the stratigraphic and radiocarbon analysis of deposits from Lake Keilambete, located within the western Victorian volcanic province near Kerang 190 km west-south-west of Melbourne (Fig. 1).

The lake occupies the crater of a maar—a volcanic eruption crater lying below the general level of the surrounding country

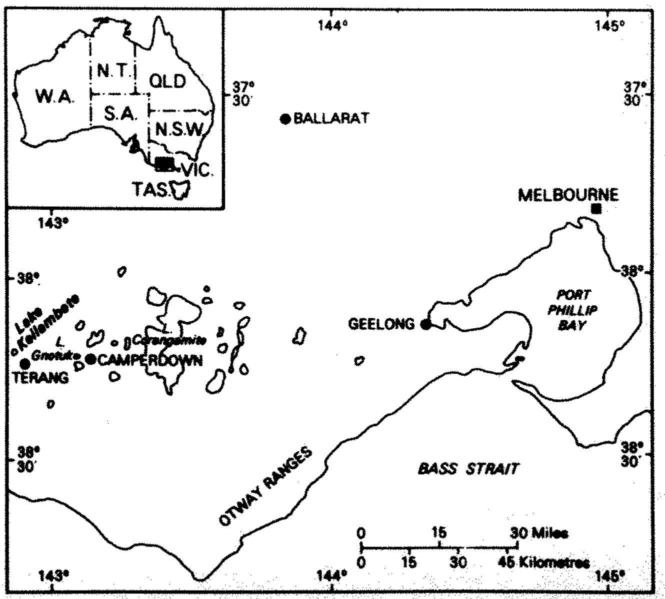

Fig. 1 Diagram showing location of Lake Keilambete.

and surrounded by a low tuff ring. The crater forms an internal drainage basin 1.8 km in diameter; it has a catchment area of 4.2 km^2 and is controlled by a relatively simple hydrologic system. Lake level responds sensitively to changes in precipitation or evaporation and lake sediments offer a means of reconstructing the sequence of climatic oscillations in late Quaternary time.

The lake derives water from three sources: direct precipitation, runoff from the crater slopes, and a small (almost negligible) ground water increment. Water is lost by evaporation alone as a thick clay effectively prevents water loss through the lake floor. During former high water phases, overflow may have occurred through the lowest point of the crater rim.

Throughout the period of European settlement, the crater has remained filled with water but has not overflowed. Compared with the low salinities of the contributing waters, the high salinity of the lake (60,000 p.p.m.) indicates that it has remained a closed basin for a long time. Lake stratigraphic data are available from two sources. First, around the margins of the lake, partly lithified lake deposits unconformably overlie Miocene calcarenite, the local bedrock of the region. Near the water's edge approximately 6 m of coarse, bedded and rounded detritus alternates with fine white marls. The coarse detritus is reworked volcanic fragments and contains lacustrine mollusca (*Coxiella* and *Limnea*). It is interpreted as a shallow lake deposit. The marls resemble carbonates forming in the lake today. Second, a series of ten cores taken from the shoreline out towards the deepest part of the lake provides a record of the recent lake deposits.

Table 1 Radiocarbon Dates from Lake Keilambete*

Lab. No.	Description	^{14}C age (yr BP†)
N-517	11 to 21 cm, core 4	610±110
N-518	21 to 33 cm, core 4	935±110
N-390	Tree submerged by lake waters and overlain by lacustrine sediments	1,890±115
N-519	55 to 65 cm, core 4	1,970±110
N-520-1	79 to 90 cm, core 4	2,410±120
N-521-1	102 to 112 cm, core 4	2,600±110
N-522-1	130 to 140 cm, core 4	2,970±120
N-523-1	165 to 175 cm, core 4	3,580±125
N-524-1	190 to 200 cm, core 4	4,200±125
N-525-1	235 to 245 cm, core 4	5,250±135
N-526-1	290 to 300 cm, core 4	6,440±145
N-527-1	325 to 345 cm, core 4	7,850±165
N-528	395 to 412 cm, core 4	14,300±300
ANU-199	Carbonate from upper marl below disconformity	20,340±500
N-567	Carbonate from upper marl band interbedded in reworked volcanic agglomerate	21,600±650
N-566	Carbonate from marl near base of lake sequence	29,100±1,250

* Data from refs. 1 and 2.

† Except where specified, all dates were obtained from total organic carbon.

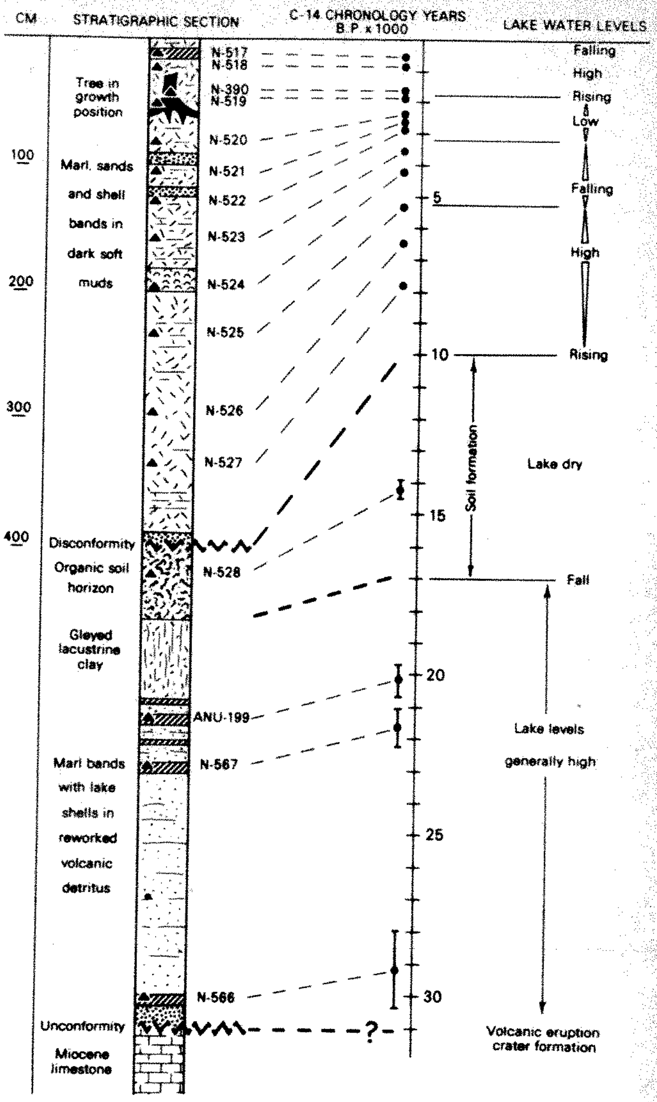

Fig. 2 Generalized stratigraphic section through sediments of Lake Keilambete showing ^{14}C chronology and sequence of reconstructed water level oscillations. Standard age deviations are shown only when values exceed ±250 radiocarbon years.

The stratigraphic section (Fig. 2), generalized from both outcrop and core sequences, reveals a basal unit of volcanic agglomerate and marl representing earliest lake deposits on which a soil horizon has formed. This is disconformably overlain by a 4 m sequence of unconsolidated, dark, organic-rich muds which alternate with pale carbonate bands. This upper unit was deposited since the last major drying, represented by the soil horizon below 400 cm.

Within the upper unit several sandy horizons in the otherwise fine textured deposits denote important facies variations related to changes in water level. In present day lake sediments, sands similar to those at 100, 125 and 400 cm (Fig. 2) are restricted to water depths of less than 3 m while clays are characteristic of deeper water. Assuming that the depth control of texture found in the relatively simple hydrodynamic system of the lake today also applied in the past, alternations of coarse and fine sediments in the cores can be directly related to past water level oscillations. Moreover, the occurrence of organic matter throughout the upper unit permits the facies variations to be accurately dated, thereby establishing the age of the oscillations and of the hydrologic changes which controlled them.

Radiocarbon dates representing 10 cm vertical thicknesses were obtained from core samples throughout the upper lake muds, from organic material in the buried soil horizon and from lake marls in the lower lithified unit. Additional ^{14}C analyses of carbonates from the upper lake muds[1] will be discussed elsewhere. The radiocarbon dates (Table 1) form a consistent series. Moreover, the ^{14}C ages of organic remains in the upper muds are consistent with ages based on estimated rates of deposition. They show no measurable initial error due to incorporation of old carbon into the organic content. The basal lacustrine sediments indicate that lake-full conditions existed from about 30,000 BP until after 18,000 BP. Some time between 15,000 and 18,000 BP the lake dried and remained in this state for several thousand years, long enough to permit soil development on older lake sediments. Ephemeral swampy conditions probably existed at this time.

The age of the next water level rise, estimated by extrapolating the ^{14}C ages to the base of the cores (assuming approximately constant rates of deposition), began about 10,000 BP.

The lake then remained deep for several thousand years and may even have overflowed. About 5,500 BP a change in the hydrologic environment is reflected in an increase in carbonate production and the eventual coarsening of bottom sediments, culminating in the deposition of shallow facies at 3,100 BP. At 3,100 BP water level rose slightly and then fell again, maintaining this low position until about 2,000 BP. Trees found in positions of growth near and below present water level and dated at 1,890 BP (N-390) were submerged by rising waters at this time. The trees belong to the last period when water level was below that of today. The lake rose and remained deep until after European settlement. In the late nineteenth century it began to fall and in 1969 stood at its lowest level for the past 1,900 yr.

In nearby Lake Gnotuk, submerged trees have been dated at 1,865 ± 85 BP (GX-0149, E. D. Gill, personal communication). Synchronous oscillations in lakes 20 km apart provide strong evidence that the controlling factor was climate rather than local hydrologic variations. Furthermore, the major drying between 18,000 and 15,000 BP is in close agreement with evidence documented from lakes in different hydrologic settings in north Victoria and south-west New South Wales recorded by J. M. B.[3]. The rise at about 10,000 BP, reflecting an increase in precipitation or decrease in temperature, cannot yet be correlated accurately with events elsewhere in Australia, although Kershaw[4] suggests a wet period in north Queensland at this time.

Effects of a Post-Glacial thermal maximum are weakly represented by a slow fall in water level and a corresponding rise in carbonate production from 5,500 to 3,100 BP. The magnitude and implied rates of these changes suggest conditions little different from those in the area today. The data therefore do not support the hypothesis of widespread Post-Glacial aridity so widely claimed in Australia[5–7]. Although temperatures from 5,500 to 3,100 BP may have been slightly higher than in the preceding interval, the degree of aridity would almost certainly not have been sufficient to cause the vegetation destruction and widespread landscape instability which are sometimes attributed to events of this time.

Conditions moderated at 3,100 BP when a slight rise of lake level occurred, but the major rise marking the beginning of the next relatively wet period did not occur until 1,900 BP.

Oscillations in Lake Keilambete can be matched in other lakes in a variety of settings in south-east Australia supporting the interpretations of the water level changes discussed here. The sequence of palaeoclimatic conditions probably has general application through south-east Australia and it may help provide a reliable basis for climatic correlations within Australia and between different continents in both hemispheres.

We thank Mr J. N. Jennings and Mr C. D. Ollier who read and criticized the manuscript, and Mr Keith Mitchell for drawing the figures.

Asbestos Fibres in Beverages and Drinking Water

THE hazards of inhaling asbestos fibres[1–4], the high incidence of gastrointestinal cancer[1,2,5–7] and abdominal neoplasms[3,8,9] among asbestos workers and the fact that asbestos fibres may penetrate the mucosa of the stomach and the intestine of animals[10,11] are known and so it is important to study the distribution of asbestos fibres in the environment. Asbestos fibres have already been found in beer[12], and the occurrence of fibres 0.5 nm in length and 0.01 nm in diameter suggests that such material may find its way through filtering systems into city drinking water supplies, and this we have been able to confirm.

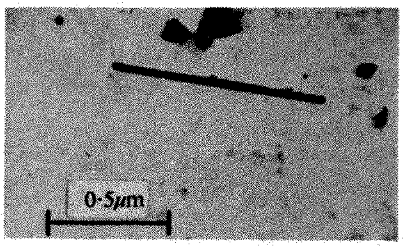

Fig. 1 Electron micrograph of asbestos fibre isolated from beer (enlarged 31,000 times).

The asbestos fibres in 400 ml. samples of beverages and water were concentrated by centrifuging in excess of 16,000*g*, drying at 100° C and ashing at 500° C[12]. The ash was taken up in 1 ml. of distilled water and agitated in an ultrasonic vibrator to disperse the fibres and ash particles[12]. Five µl. of this dispersion was evaporated with the aid of a heat lamp on 200 or 400 mesh carbon coated copper grids. Using a Siemens Elmiscop IA electron microscope at 80 kV and a magnification of 20,000, the number of fibres in each of five or ten grid holes was counted, and corrected for dilution. Precautions were taken to prevent contamination of samples from extraneous airborne fibres and no fibres were detected in distilled water

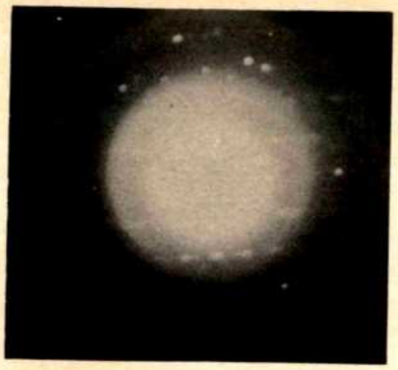

Fig. 2 X-ray diffraction pattern of asbestos fibre shown in Fig. 1.

blanks which were treated in the same manner as the liquid samples.

Twelve brands of Canadian beer, wine, sherry and port, six of American beer, six of European wine, vermouth and sherry and two of South African sherry were examined and all were found to contain asbestos fibres. Counts made on some of these brands are reported in Table 1. The fibres in Canadian beer (Fig. 1), sherry and water were identified as being chrysotile asbestos by comparing their electron diffraction pattern (Fig. 2) with that of pure chrysotile asbestos. Some of the European samples contained fibres of amphibole asbestos. Many asbestos fibres were hidden in clumps of debris such as mineral matter in water and diatomaceous earth which is used as a filtering aid in beer. As a result, the number of fibres reported in Table 1 must be considered a minimum estimate of those actually present. Most of the fibres found in Canadian beer and in filtered city water were less than 1 µm in length while most samples of wine, some American beer and unfiltered melted snow or river water also contained a considerable number of asbestos fibres ranging from 1 to 15 µm in length.

Tap water from three major Canadian cities, Ottawa, Toronto and Montreal, combined from 2.0 to 4.4 million fibres per litre. All of these cities have filtration systems and Ottawa tap water, drawn from the Ottawa river, had considerably fewer fibres than unfiltered river water. Many of Canada's major asbestos mines are located in the Eastern Townships of Quebec and filtered tap water from towns in this area did not differ greatly from that in the larger cities but unfiltered tap water in Thetford Mines, drawn from a small lake in the heart of an asbestos mining area, was exceptionally high in fibre content. The high level of asbestos fibres in melted snow in the Ottawa area gives some indication of one source of asbestos in surface waters.

The question as to the hazard of orally ingested asbestos has not yet been resolved. The amounts by weight of the asbestos found in these samples were exceedingly small—about 1 µg per 10 million fibres—obtained from counts on 1 mg samples of fibres of approximately the same size as those found in the beverages and water. Further work is required to determine the extent to which the fibres penetrate the walls of the digestive tract, the degree to which they may be transported to other organs of the body and the biological effects of their residence in various tissues. Studies of this nature are now in progress.

We thank Mr D. Campbell and Mr G. Bergeron for technical assistance and the Food and Drug Directorate, Department of National Health and Welfare, Ottawa, for obtaining the water samples.

BIOLOGICAL SCIENCES

Molecular Conformation of Deoxyuridine

THE structure determination of deoxyuridine was undertaken as part of a series of conformational studies of nucleic acid components. Such studies give information about the preferred conformation of nucleosides and nucleotides[1,2], and may clarify the conformational differences and changes that occur in nucleic acids. The conformational parameters of interest in deoxyuridine are the pucker of the sugar ring, the torsion angle of the sugar relative to the base about the glycosidic bond and the orientation of the C(5′)–O(5′) bond about the C(4′)–C(5′) bond.

In ribose and deoxyribose nucleosides, the most common type of pucker of the sugar is either C(2′) endo or C(3′) endo. In the deoxynucleosides the C(2′) endo pucker is by far the most common. Since one of the nucleosides with a C(3′) exo pucker is thymidine[3] it was of particular interest to know whether deoxyuridine would also have this type of pucker. Even the same nucleoside in different environments can have a different type of pucker[4], but these differences have only been observed in ribose nucleosides. There is therefore a need for further studies of deoxy nucleosides and nucleotides.

Crystals of deoxyuridine were obtained from aqueous solutions. The unit cell is monoclinic with dimensions $a=7.91$ Å, $b=6.71$ Å, $c=18.77$ Å, $\beta=96.6°$ and the space group is $P2_1$. There are four molecules in the unit cell and therefore two molecules in the asymmetric unit. Intensity data were collected with a Hilger and Watts linear diffractometer using molybdenum Kα radiation. The structure was solved by Patterson interpretation methods. The first step was the determination of the orientation of the plane of the pyrimidine bases in the unit cell using the $I(\theta,\varphi)$ function of Tollin and Cochran[5]. The orientation of the pyrimidine base within the plane was determined by means of a rotation function[6], and the positions of the molecules relative to the 2_1 axis were found using the $Q(X_0Z_0)$ function of Tollin[7]. Full details of the structure determination will be given elsewhere. The R factor at the present stage of refinement is 0.08.

The conformation of both molecules in the asymmetric unit is very similar. The pucker of both sugars is C(2′) endo, or C(2′) endo–C(3′) exo with respect to the three-atom plane C(1′)–O(1′)–C(4′). Displacements of the C(2′) atoms in molecules I and II relative to this plane are 0.508 and 0.383 Å respectively, and of atoms C(3′) they are 0.111 and 0.210 Å respectively. Thus the sugar pucker in deoxyuridine is like that in the majority of deoxynucleosides and differs from that in thymidine.

The glycosidic torsion angle, φ_{CN}, defined by Donohue and Trueblood[8], is $-28°$ in molecule I and $-24°$ in molecule II.

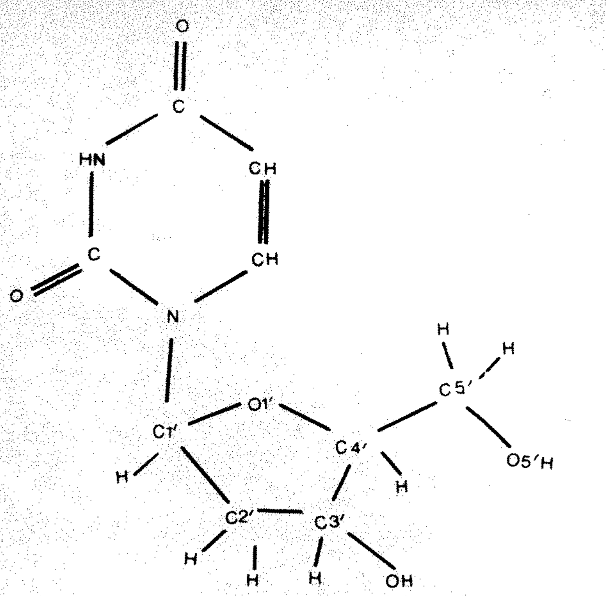

Fig. 1 The chemical structure of deoxyuridine.

Thus both molecules are in the *anti* conformation. A survey of nucleosides and nucleotides shows that the preferred conformations are such that in general the φ_{CN} value is larger for a C(2′) endo pucker than for a C(3′) endo pucker[1,2,4]. The values of φ_{CN} in deoxyuridine, however, are smaller than those found previously for C(2′) endo puckers and indicate that the preferred ranges of φ_{CN} values overlap.

In both molecules the orientation of the C(5′)–O(5′) bond is *trans* with respect to the C(4′)–O(4′) bond, and *gauche* with respect to the C(4′)–C(3′) bond. This *trans–gauche* conformation also occurs in fluorodeoxyuridine[9] and iodouridine[10], and energetically is just as favourable as the more common *gauche–gauche* conformation[11]. Indeed, the conformation of the C(5′)–O(5′) bond in those deoxynucleosides which contain uracil shows the three types of preferred conformations for this bond, as shown in Table 1, which summarizes the conformational parameter in these nucleosides.

Table 1 Conformational Parameters of the Nucleosides

Nucleoside	φ_{CN}	Sugar conformation	C(5′)–O(5′) conformation
Fluorodeoxyuridine[9]	−59°	C(2′) endo	*trans-gauche*
Bromodeoxyuridine[12]	−47°	C(2′) endo	*gauche-trans*
Iododeoxyuridine[13]	−63°	C(2′) endo	*gauche-gauche*
Thymidine[3]	−39°	C(3′) exo	*gauche-trans*
Deoxyuridine I	−28°	C(2′) endo	*trans-gauche*
Deoxyuridine II	−24°	C(2′) endo	*trans-gauche*

We thank Dr P. Tollin, Dr D. W. Young and Mr A. R. I. Munns for discussion and advice, and Mr J. Low for assistance with the data collection. We also thank the Science Research Council for the diffractometer and the Medical Research Council for financial support.

Pole Figures of the Orientation of Apatite in Bones

The orientation of the apatite and collagen in bone was first considered in this work because of its significance in the possible piezoelectric effect in bone. Bone is a polycrystalline material composed chiefly of apatite and collagen, and crystals of a component must be both piezoelectric and orientated in order to produce an overall piezoelectric effect. Orientation studies are also important for an understanding of the mechanical properties and anisotropic characteristics of bone as a structural material. Biologically, bone is a tissue composed of lamellae, blood, bone cells and fluids in a continual state of change. Within this biological system, however, could be a three dimensional network of apatite and collagen on a much smaller scale, which would maintain the mechanical properties of the bone at a constant level, irrespective of the normal sequence of biological changes. This work shows that such a highly organized three dimensional mesh of apatite crystals does exist, and that the exact structure of the mesh in a particular bone may be related to the function of that bone.

Other workers found that apatite crystals were orientated along the length of long bones. Clark and Iball[1], using the film method, reported that the apatite crystals in rat femur were aligned parallel to the axis of the shaft, and also in a transverse plane, tangential to the bone surface.

In this work, preliminary orientation studies of rat bone were made using the film method. Arcing of the 002 powder ring when the X-ray beam was normal to the length of the bone indicated that some apatite crystals were orientated along the length of the bone. When the X-ray beam was parallel to the length of the bone the patterns seemed inconclusive. A more accurate method of determining orientation was required to determine accurate pole figures which would demonstrate the three dimensional arrangement of apatite crystals in bone. A Schulz texture goniometer was used and the pole figures were plotted by computer. This method was originally developed for orientation studies in polymers[2].

The pole of a set of planes in a crystal is the point where the normal to the planes intersects an enclosing sphere. A pole figure of a particular set of planes is a stereographic projection of such a sphere, on which equal intensities of all poles are contoured. Thus the peaks on a pole figure represent the directions of maximum distribution of the poles of a set of crystal planes. Suitable planes to use were determined by preliminary film and diffractometer work. Planes with a θ Bragg angle well isolated from other peaks give optimum results. In the case of apatite, 002 is a good reflexion and, as it is a basal plane, it has the further advantage that it is comparatively easy to interpret. The prismatic plane (310) was also used because two reflexions incorporating all three indices are necessary to determine completely the orientation of a crystal.

The intensity of the diffracted beam was measured by a proportional counter and recorded on a chart recorder, and was proportional to the distribution of poles in that direction. To produce a pole figure, 720 intensities were read off the chart and the levels of equal intensity contoured by a computer plotter.

Pole figures of the shaft of a bovine femur and of the frontal bone of a bovine skull are shown in Fig. 1*a* and *b* respectively. The orientation of the bone specimen with respect to the pole

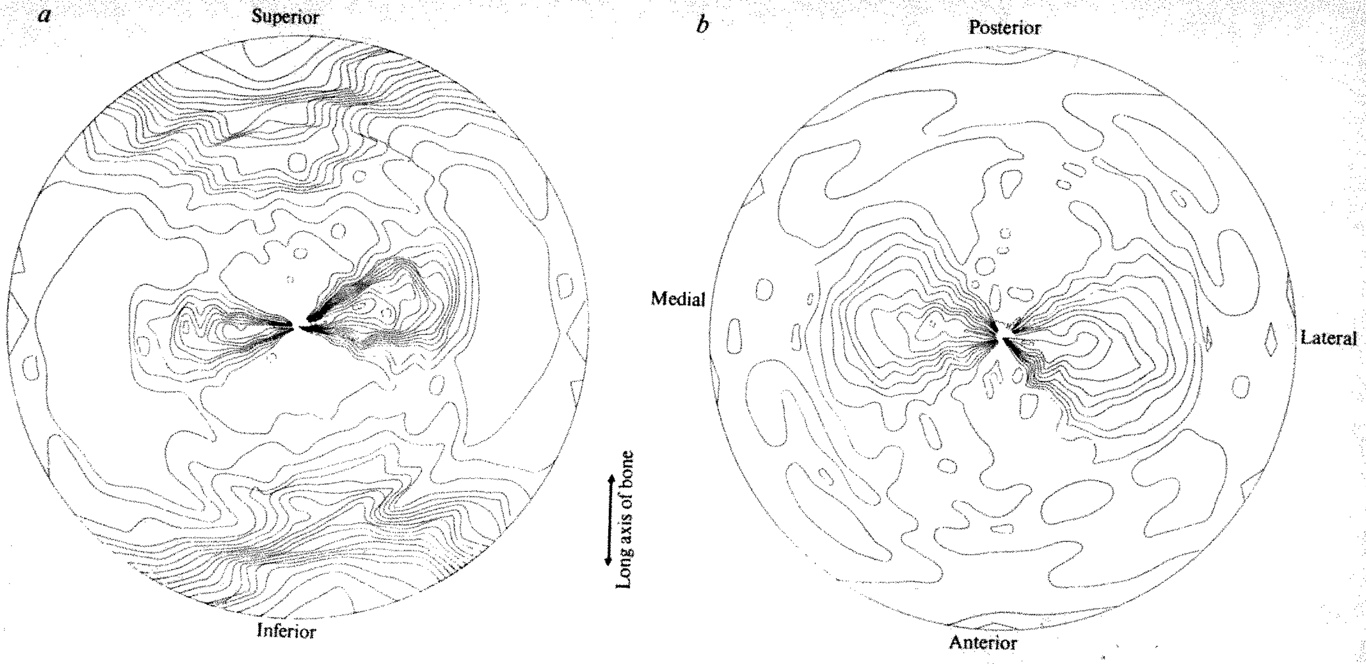

Fig. 1 *a*, 002 pole figure of the apatite crystals in a longitudinal section of the shaft of a bovine femur; *b*, 002 pole figure of the apatite crystals in a tangential section of the frontal bone of a bovine skull.

figure is shown on its periphery. The high peaks of intensity at the north and south poles of the femur 002 pole figure indicate that the long axis of the shaft of the femur is the main direction of orientation. The results also reveal an orientation which is perpendicular to the length of the bone and radial to the long axis. Further, the distribution about this direction is in a characteristic figure-of-eight configuration, which recurs in all the pole figures so far plotted. By contrast, the main orientation direction in the frontal bone of a bovine skull is normal to the surface of the bone. Again, the distribution of intensities about this direction is in the form of a figure-of-eight. There is a considerably smaller distribution in a direction roughly posterior–anterior in the plane of the bone.

Histological slides were prepared from pieces of the femur and skull bones taken as closely as possible to the specimens used for the pole figures. The osteons were orientated along the length of the femur, and tangentially to the surface of the frontal bone of the skull. There is thus a correlation between the osteon orientation and the pole figures for apatite.

In each pole figure the osteon direction is roughly north–south. Thus in the femur the distribution of apatite crystals along the length of the osteons seems to be dominant, but there is also a comparatively strong orientation in a direction perpendicular to the osteon axis. In the skull, the orientation of the apatite is dominantly perpendicular to the osteon axis. This indicates an adaptability of the apatite distribution to the differing mechanical roles of the two bones.

We thank Professor J. M. Zarek for suggesting the topic of this work and for helpful advice, and M. J. Dickens for preparing the histological slides. The work was supported by the Medical Research Council.

Non-surgical Assessment of Cardiac Function

Cardiac catheterization to evaluate myocardial or valvular function should not be used in the seriously ill patient and is difficult in the infant[1]. Furthermore, its use is justified for neither periodic screening examinations nor for routine monitoring at surgery. The clinical value of continuous monitoring of a parameter closely related to myocardial efficiency during and immediately after surgery cannot be over-emphasized. The social implications of the ability to screen for valvular disorders and decreased myocardial efficiency before infarction are more difficult to predict.

The close proximity of the mediastinal vessels, especially the aortic arch, to the oesophagus has stimulated the development of an ultrasonic Doppler shift oesophageal probe as a non-surgical technique for estimating aortic arch blood velocity in the conscious patient. The probe consists of an oesophageal tube near the tip of which is inserted a small 'Perspex' mount carrying a piezo-electric disk of 5.0 mm radius. Both faces of the disk are coated with conducting paint and a scratch is made across the diameter of one face, thus electrically separating the crystal into transmitter and receiver. The intact surface on the opposite face forms the common earth electrode. Wires are soldered directly to these three surfaces using low melting point solder (flux 362, alloy, TLC, Multicare Solders Ltd) before passing through the lumen of the oesophageal tube to a Parks 805 flowmeter. Ultrasound is generated continuously by the transmitter part of the crystal which is excited by an rf oscillator to produce a beam of power $\simeq 30$ mW cm^{-2}. Ultrasonic waves are scattered from moving particles such as blood cells in the path of the beam. The frequency of the back-scattered ultrasound detected by the receiver crystal is Doppler shifted by an amount (Δf) related to the particle velocity (v) by

$$\Delta f = \frac{2fv \cos \varphi}{c}$$

where f is the frequency of the emitted ultrasound, φ the angle between the ultrasonic beam and the path of the particle and c the velocity of the ultrasound in the intervening tissue.

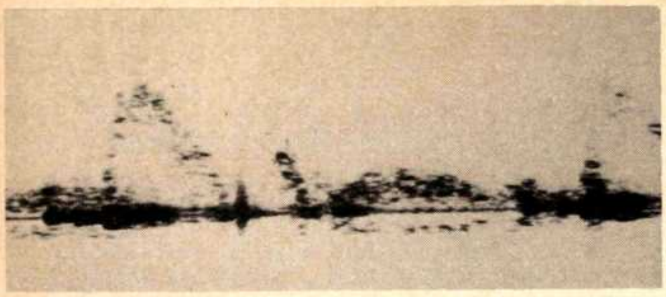

Fig. 1 Spectral analysis of Doppler shift signals from the descending thoracic aorta. The sonagram shows frequency as ordinate against time as abscissa with blackening of trace proportional to amplitude of each frequency component. The second peak represents reverse flow and the high amplitude low frequency components are due to arterial wall movements.

Using an excitation frequency of 5 MHz, the Doppler shift frequencies at each instant are detected as a range of audio signals corresponding to the range of particle velocities in the path of the beam. The problems of analysing such a spectrum of signals have been discussed[2]. To some extent the problems are reduced by the bluntness of the velocity profile in the upper thoracic aorta[3], so that the maximum frequency envelope of the sonagram of signals originating from the aortic arch approximates to the mean velocity across the spectrum (Fig. 1).

Alternatively, if the audio signals are fed into a zero-crossing frequency meter, an uncalibrated velocity-time pulse can be displayed on an oscilloscope screen or on a chart recorder. Although the trace is uncalibrated, turbulence caused by a stenotic aortic valve can be detected and percentage regurgitation can be estimated directly from the records. In addition, beat to beat changes in the flow pattern and peak velocity and acceleration can be of considerable value to the surgeon by giving immediate warning of deteriorating cardiac efficiency. The accurate measurement of the flow velocity and its quantitative relationship to myocardial function is the subject of our current work.

The work was supported by a grant (to C. D. S.) from the Medical Research Council, and the Wellcome Trust as part of a general study on pulsatile flow (R. G. G.).

Lithium attenuates Drug-induced Hyperactivity in Rats

LITHIUM salts have been used in psychiatry for more than 20 yr, especially for treating manic behaviour[1], and recently there has been a resurgence of interest in these compounds both as a specific treatment of mania and as prophylactics against manic-depressive illnesses in general[2,3].

Few systematic behavioural studies, however, seem to have been carried out on animals in controlled experimental situations[4-7], possibly because effects on behaviour of non-toxic doses are difficult to demonstrate in 'normal' animals. If rats are given some combinations of dexamphetamine with amylobarbitone or chlordiazepoxide they show a characteristic and prolonged hyperactivity in novel environments, which cannot be induced by any dose of the separate drugs[8,9]. The hyperactivity consists of persistent and apparently stereotyped walking in a maze, and is elicited with great reliability. Because one aspect of mania is increased motor activity, we thought that the hyperactivity induced by the mixture could provide a suitable baseline for testing behavioural effects of lithium in animals. Chronic as well as acute treatments of lithium were given; usually several days are needed for lithium to exert therapeutic effects in manic patients.

We used naive hooded female rats approximately 120 days old at the beginning of the experiments which had been reared in standard conditions of lighting, temperature and humidity and had not been handled since weaning. In chronic experiments rats were injected with either 3 mequiv./kg of lithium chloride (LiCl, isotonic solution), or with the same amount of isotonic saline intraperitoneally daily, always at the same time in the morning, for 15 days. On the fifteenth day, the rats pretreated with LiCl received their last dose (chronic lithium group); those pretreated with saline were divided into two sub-groups: one received its usual morning injection of saline, and the other was given a single injection of 3 mequiv./kg LiCl (acute lithium group). Three hours later all rats were injected subcutaneously with either a mixture of 12.5 mg/kg chlordiazepoxide and 1.18 mg/kg dexamphetamine, dissolved in saline, or with saline (2 ml./kg) alone. Thirty-five minutes after this injection the rats were placed singly in symmetrical Y-shaped mazes, and their behaviour was scored for 5 min, as: (1) the number of times the rats entered the arms of the maze with all four feet across the entrance ("entries"); (2) the number of rears; (3) number of faecal boluses deposited, and the presence or absence of urine in the maze. The observers also rated the ataxia of the rats' walking, using a six point scale. At the end of the Y-maze trial, the rats were anaesthetized with pentobarbitone, blood was withdrawn from the descending aorta, and lithium content was assayed with a flame-photometer (EEL) using a standard method[10].

In further acute experiments the same sequence of operations was followed as that on the last day of the chronic experiment except that: (1) in the morning all rats were injected with 2 mequiv./kg of LiCl (instead of 3 as in the chronic experiments) or the same amount of NaCl; (2) during the second part of the experiment, apart from rats which received subcutaneous injections of saline or of the drug mixture, other groups were given one or other of the constituent drugs, that is, either 12.5

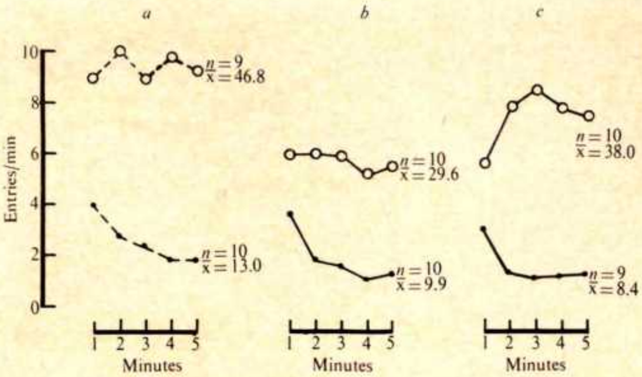

Fig. 1 Effects of acute and chronic LiCl (3 mequiv./kg) on hyperactivity induced in rats by a mixture of 12.5 mg/kg chlordiazepoxide and 1.18 mg/kg dexamphetamine. Group (*a*) received fifteen daily injections of saline; (*b*) fourteen injections of saline and one of LiCl; and (*c*) fifteen injections of LiCl. The rats were tested in a Y-maze either with the mixture (○) or with saline (●). The single injections of LiCl (*b*) significantly reduced the hyperactivity; chronic pretreatment with LiCl (*c*) had very little effect. No significant differences were found among saline controls.

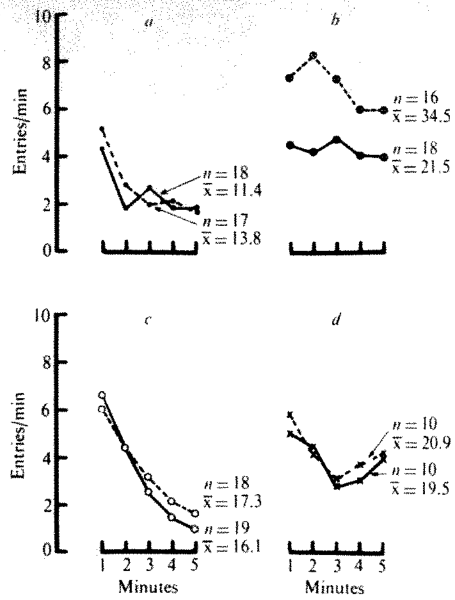

Fig. 2 Effects of a single dose of 2 mequiv./kg LiCl on spontaneous activity of rats under the influence of (*a*) saline, (*b*) a mixture of 12.5 mg/kg chlordiazepoxide and 1.18 mg/kg dexamphetamine, (*c*) 12.5 mg/kg chlordiazepoxide and (*d*) 1.18 mg/kg dexamphetamine. As in Fig. 1, a single injection of lithium had no significant effects on the number of entries into the arms of a Y-maze by rats unless they were made hyperactive by the drug mixture (*b*). ——, Rats given 2 mequiv./kg isotonic LiCl 3–5 h before testing; - - -, rats given the same amount of saline.

mg/kg chlordiazepoxide alone, or 1.18 mg/kg dexamphetamine. Otherwise the same experimental procedures were followed throughout.

In the chronic experiments it was found (Fig. 1) that the animals which had been pretreated with saline for 15 days and had then received the drug mixture showed a near four-fold increase in the number of entries as compared with their own controls ($P < 0.001$, Fig. 1*a*). The rats pretreated with saline which were given the single dose of LiCl and then the mixture on the test day (Fig. 1*b*) were less stimulated (Student's *t* test, $P < 0.05$, two tailed). In the chronic lithium group the reduction in the drug mixture-induced hyperactivity was negligible (Fig. 1*c*). There were no significant differences among the three saline control groups. Thus only acute lithium treatment significantly reduced the hyperactivity.

Because animals tested with 3 mequiv./kg showed some signs of toxicity, for example, diarrhoea, the dose was reduced to 2 mequiv./kg for the next acute experiments (Fig. 2). The mixture again produced a marked, almost three-fold, increase in activity ($P < 0.001$, Fig. 2*b*) and, as before, lithium treated animals which were tested under the influence of the mixture were less active ($P < 0.01$) than mixture animals pretreated with saline. The single lithium pretreatment did not, however, alter the activity of the saline controls (Fig. 2*a*). It is clear that acute pretreatment with this dose (2 mequiv./kg) of lithium chloride, as in the previous experiment with 3 mequiv./kg, mitigated though did not completely abolish this particular form of drug-mixture induced hyperactivity; in both cases the number of entries was reduced by approximately a third. The higher levels of activity with the mixture alone in the chronic experiments may have been due to handling; some forms of handling have previously been found to have a similar effect[11].

Mixture treated animals were hyperactive in spite of motor incoordination and flaccidity which were reflected in high ataxia ratings made by the observers. Lithium did not increase ataxia ratings in any of the groups. It therefore seems unlikely that the reductions in activity with lithium in the mixture groups can be explained by muscle weakness, although this is frequently reported as a side effect in lithium therapy. As expected, lithium-treated animals urinated more than their controls during testing although the differences were not statistically significant.

Plasma lithium levels after acute administration of 3 mequiv./kg LiCl were 1.06 ± 0.258 mequiv./l. (mean ± s.d.) in the mixture and 0.83 ± 0.099 in the saline groups; the corresponding levels in the chronic groups were 0.69 ± 0.166 and 0.84 ± 0.106. Thus after acute administration plasma levels with the mixture were higher than with saline ($P < 0.05$), and considerably higher than with the mixture after chronic lithium pretreatment ($P < 0.01$).

The mean plasma lithium levels after acute 2 mequiv./kg pretreatment were: 0.49 ± 0.089 (mean ± s.d.) with saline; 0.52 ± 0.178 with chlordiazepoxide and 0.52 ± 0.144 with dexamphetamine, and 0.67 ± 0.197 with the mixture. The separate drugs did not increase plasma levels but, as before, the levels were increased by the mixture ($P > 0.05$). The results with acute lithium therefore seem to indicate that in the two doses used lithium does not have any marked depressant effect on the spontaneous activity of rats unless the animals have been made hyperactive. Our results are consistent with a study in which lithium inhibited a form of behaviour induced by a combination of desmethylimipramine and Ro 4-1284 (a reserpine-like drug) but it did not inhibit excitation and increased stereotyped behaviour induced by amphetamine alone[5].

Evidence has been accumulating that acute or short term lithium treatment reduces the amount of noradrenaline available for interaction at receptor sites[12,13]. The biochemical effects of chlordiazepoxide–dexamphetamine mixtures are not yet established, but in addition to the well known sympathomimetic actions of dexamphetamine, chlordiazepoxide has been found to lower noradrenaline turnover in the brain[14]. Thus it is possible that the mixture-induced hyperactivity depends on noradrenergic mechanisms which are affected by acute lithium treatment. This suggestion is supported by the finding that chronic lithium does not markedly alter hyperactivity induced by the mixture nor does it affect noradrenaline turnover in the brain[15–17]. Patients have been reported to excrete much less lithium during manic episodes[18,19]; in our experiments the animals which would have been hyperactive with the drug mixture showed higher concentrations of lithium in the plasma; this may suggest that they also excreted less lithium than animals which were not given the mixture. To that extent results from our acute experiments reflect the clinical situation. In humans, however, lithium usually reduces manic behaviour only after at least several days of treatment, whereas in our experiments chronic lithium was relatively ineffective in mitigating the mixture induced hyperactivity, nor did the mixture increase plasma levels.

We are now testing the effectiveness of lithium against various forms of hyperactivity induced by other means, including by different drugs, by brain lesions and by behavioural manipulations, in order to investigate further the generality of our findings and the possible mechanisms involved.

We thank Drs D. H. Jenkinson and A. V. Juorio and Professors M. Maizels, H. McIlwain and H. O. Schild for valuable comments and discussion and D. U'Prichard, D. I. Carruthers-Jones and Terri Miller for help with experiments. Procoagulant Synthesis by Cultured Fibroblasts triggered by Cell Adhesion

SYNTHESIS of a potent procoagulant by cells in tissue culture has been demonstrated but its identity is obscure[1]. Activity is low at the beginning of culture of normal human fibroblasts and increases several hundred-fold after 12–24 h of incubation at 37° C. This increase is readily detected by the one-stage assay for factor VIII (antihaemophilic globulin) but can also be demonstrated by the two-stage factor VIII assay based on the thromboplastin generation test. Studies in progress to characterize this procoagulant have demonstrated a marked increase of factor XI as well as factor VIII activity and evolution of factor XI activity during contact activation with celite. Increase in activity detectable in the one-stage assay for factor IX and XII was much less. The procoagulant was incapable of clotting a fibrinogen solution and no change in assays for factor V and VII was observed during culture.

These data suggest a relationship of this procoagulant to first-stage coagulation factors, particularly factors VIII and XI. But identification (by *in vitro* coagulation tests) of specific coagulation factors within cells is necessarily complicated by the presence of other procoagulant substances such as phospholipid and tissue factor. Evaluation of the latter is so far incomplete. *In vivo* infusion studies and coagulation factor identification by immunological methods as well as by further *in vitro* testing will be reported in detail elsewhere.

In previous studies considerable variability in procoagulant production was observed between cultures of various cell types[1]. Suspension cultures of leucocytes generated procoagulant levels much lower than observed in monolayer cultures. Furthermore, the increase in procoagulant activity in monolayer cultures of several cell types was independent of cell doubling time and paralleled the period during which cells were becoming adherent to the flask. Attention was thus drawn to the process of cell adhesion as a possible triggering mechanism for procoagulant synthesis.

Procoagulant production was studied in cultures of human foreskin fibroblasts prepared in fresh medium at various cell concentrations. Maximum levels were achieved with a cell concentration of 2×10^5/ml. By contrast, cultures established at a concentration of 4×10^5/ml. yielded procoagulant levels of approximately 50% of cultures established at the lower cell concentration. Cells in a concentration of 4×10^5/ml. formed a virtual monolayer from the outset. There was little surface on which the potentially adherent cells could spread.

To investigate further the possible relationship between cell adhesion and procoagulant synthesis, cell cultures were prepared in a concentration of 2×10^5/ml. in disposable plastic culture flasks (Falcon) and either allowed to remain at rest or placed on a mechanical shaking device to prevent cell adhesion. All cultures were carried out at 37° C. The tilt-top mixer (Lab-Tek aliquot shakers, model 4651, Ames Co., Elkhart, Indiana) rotated through an angle of 80 degrees at a frequency of 20 c.p.m. Periodic observation of cultures by inverted microscopy revealed virtually complete adherence of cells in stationary culture after 4–6 h of incubation. Thereafter rare cells were observed in suspension and haemocytometer cell counts performed on the medium were virtually zero. Conversely, in agitated cultures few cells became adherent. Cultures removed from the mixing device after 12 h of incubation and placed at rest promptly formed monolayers and were indistinguishable from initially stationary cultures. The number of cells declined after 24 h on the shaker, resulting in a less dense monolayer when culture flasks were placed at rest.

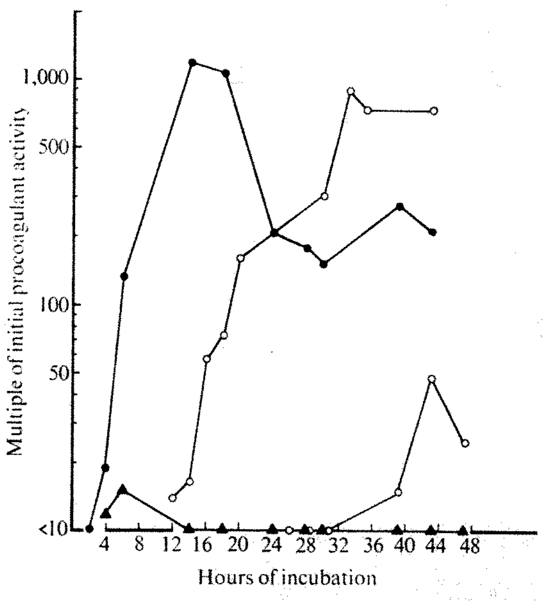

Fig. 1 Effect of shaking on procoagulant production by cultured fibroblasts. ●, Stationary cultures; ▲, cultures incubated on shaker; ○, cultures removed from shaker at 12 and 24 h.

Cells in stationary and rotated flasks were collected at intervals; the plastic flask was opened with a heating element and the monolayer was mechanically dislodged from the floor of the flask. Cell clumps were broken and cells were distributed evenly in the overlying medium by repeated passage through a Pasteur pipette and finally frozen and thawed three times in preparation for analysis. The one-stage assay for factor VIII based on the activated partial thromboplastin time was used in these experiments because it is a sensitive indicator of procoagulant production. Results of assays are presented in Fig. 1. In each of seven experiments the increase of procoagulant activity was prompt and dramatic in stationary cultures. By contrast, cultures incubated on the mixing device failed to generate procoagulant activity. Cultures removed from the mixer after 12 h of incubation and placed at rest promptly began to synthesize procoagulant as cells were permitted to become adherent to the floor of the flask. Ultimate levels equalled those achieved in initially stationary cultures. Cultures agitated for 24 h retained a definite but lesser ability to generate procoagulant when removed from the shaker and placed at rest.

These experiments demonstrate a correlation between cell adhesion and synthesis of procoagulant which is potentially important in elucidating the process of haemostasis regardless of whether the procoagulant is a specific coagulation factor, for example, factor VIII, or tissue thromboplastin. Local endothelial damage might lead to a number of surface-related events which could enhance blood coagulation locally. For example, the making and breaking of cell surface contacts are necessarily involved in cell infiltration, phagocytosis, migration and proliferation.

The mechanism by which adhesion triggers procoagulant production is obscure. The pertinent cell membrane receptor or metabolic activity responsible for procoagulant synthesis is not defined. It is unlikely, however, that the *in vivo* counterpart of this phenomenon (if such exists) would be restricted to fibroblasts. We postulate that many cell types may synthesize procoagulant *in vivo* and that such synthesis may be mediated by adhesive events occurring at cell surfaces. Perhaps enhanced adhesive activity is the common denominator uniting the host of pathological states characterized by elevated circulating levels of factor VIII. Furthermore, the association of diminished levels of factor VIII and a defect in platelet adhesiveness is well known in von Willebrand's disease. This raises the possibility that the low level of factor VIII observed in this disease is the result of a defective triggering mechanism. Alternatively, the chemical configuration on the cell which permits adhesion may be identical to factor VIII.

Mode of Action of Pollen in Breaking Resistance of *Vicia faba* to *Botrytis cinerea*

THE discovery that pollen can transform the mildly virulent fungus *Botrytis cinerea* into a destructive pathogen of broad bean and strawberry[1] poses fundamental and practical problems. One concerns the nature of the stimulants from pollen[1] because *B. cinerea* is normally unable to spread from limited lesions in broad bean leaves even in the presence of fungal nutrients[2]. Another is the mode of action of the stimulants, and particularly their interaction with wyerone acid metabolism. Wyerone acid[3] has been identified as an antifungal product of infected bean (*Vicia faba*), and its formation, activity and degradation have been suggested as important factors controlling development of *Botrytis* in *Vicia*[3,5]. If pollen extracts prevent accumulation of wyerone acid or render the fungus insensitive to the acid, support would be provided for this suggestion.

A suspension of 2×10^6 *V. faba* pollen grains/ml. of sterile distilled water was frozen at −20° C, thawed and shaken for 15 min at 21° C. This procedure was repeated and after centrifugation the supernatant was dialysed for 12 h against sterile water at 5° C. The dialysate was concentrated by rotary evaporation to the original volume of suspension. This pollen extract (*p*H 5.3) was stored at −20° C. Drops (10 µl.) of suspension of 5×10^5 conidia of *B. cinerea*/ml. sterile water or pollen extract were placed on upper surfaces of detached bean leaves. Within 5 days at 17° C in moist chambers, conidia in pollen extract caused complete degradation of the leaves, whereas those in water caused some brown flecking beneath infection droplets. From similar leaves, 5 mm diameter disks bearing infection sites were excised 82 h after inoculation, and wyerone acid was extracted, separated and estimated by solvent partition, paper chromatography and ultraviolet spectrophotometry[3]. Green disks bearing brown lesions caused by spores in water contained 56 µg of wyerone acid/g fresh weight. Black disks from spreading lesions caused by spores in pollen extract contained 97 µg/g fresh weight, so pollen extract had not prevented accumulation of wyerone acid.

Table 1 Germination and Growth of *Botrytis cinerea* in Presence and Absence of 20 µg/ml. Wyerone Acid

Test solution	Germination %	Germ-tube length (µm)
Water alone	95	50–100
Bean extract	100	500–600
Bean extract + wyerone acid	0	0
Pollen extract	100	500–600
Pollen extract + wyerone acid	100	500–600

Spores of *B. cinerea* were suspended (10^5/ml.) in water alone, and in pollen and bean[4] extracts in the presence and absence of 20 µg/ml. wyerone acid. Droplets (20 µl.) of suspensions were incubated on slides for 20 h at 20° C. Results (Table 1) show that bean and pollen extracts are stimulatory to germ tube growth in the absence of wyerone acid, but that pollen extract also apparently renders spores insensitive to wyerone acid. Separate tests showed that wyerone acid was not lost during incubation with pollen extract. The lowest concentration of wyerone acid which prevented all spore germination in pollen extract was between 500 and 1,000 µg/ml. This contrasts with the concentration of 18 µg/ml. which had a similar effect in bean extract[3].

We conclude that pollen enables *B. cinerea* to overcome the inhibitory action of wyerone acid in infected broad bean, and that wyerone acid is an important factor in normal lesion limitation. This raises questions about the mode of action of pollen in stimulating infections of strawberry fruit[1], rye leaves[6] and wheat heads[7], and also about normal mechanisms of resistance in these plants.

Coated Microvesicles in Neurosecretory Terminals of Posterior Pituitary Glands shed their Coats to become Smooth "Synaptic" Vesicles

WE have suggested that microvesicles ("synaptic vesicles") within neurosecretory terminals of posterior pituitary glands are by-products of exocytosis formed by micropinocytosis-like activity serving to recapture excess membrane, of neurosecretory granules, incorporated in the cell surface. Our view arose from the discovery of exocytotic figures in electron micrographs of these terminals and the presence, in some such figures, of indications of membrane vesiculation: caveolae with microvesicles of similar size near them[1,2]. The suggestion harmonized not only with the theoretical requirement for membrane recapture after exocytosis but with the familiar characteristics of the "synaptic vesicle" population: localization in terminal regions where hormone is released; aggregates against the cell membrane, the so called "synaptoid" formations; and increased number after stimulation. The scheme, however, was not entirely satisfactory since classical "synaptic vesicles"[3] have smooth membranes while those apparently formed by membrane vesiculation were often seen to be coated, as were the adjacent caveolae[2]. While this coating supported the interpretation of such figures as micropinocytosis-like activity (coating is believed to represent the mechanism inducing membrane vesiculation[4,5]) it required us to postulate that coated vesicles are somehow transformed into the smooth "synaptic" type[2]. We here present evidence for this transformation.

Neurohypophyses of unanaesthetized rats were exposed following decapitation[2] and fixed, according to Karnovsky[6], during electrical stimulation. This yielded many microvesicles with readily discernible coats, some complete but others apparently partial. Such microvesicles can be seen mingled with smooth "synaptic" vesicles and electron-dense neurosecretory granules in Fig. 1. A coated "caveola" is present in the plasmalemma of the fibre toward the left of this illustration.

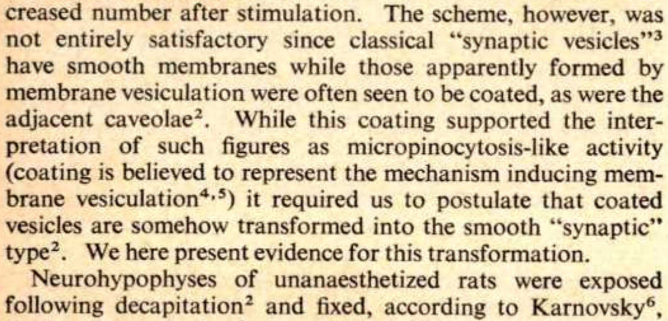

Fig. 1 Neurosecretory terminals in the posterior pituitary gland of the rat fixed during stimulation. The gland, exposed by decapitation, was stimulated electrically (28 V, 1 ms, 20 Hz) through electrodes applied to the stalk and fixed, after 2 min, without stopping stimulation, by flooding with a mixture of glutaraldehyde and paraformaldehyde at room temperature, post-fixed in osmic acid, extracted in block with uranyl acetate according to Karnovsky[6], and embedded in 'Vestopal'. This is a general view at medium magnification (× 86,000) showing, principally, terminal regions of two neurosecretory fibres abutting basement membrane. The terminals contain a fully coated microvesicle (long arrow), two half-coated microvesicles (shorter arrows), and a number of vesicles with lesser amounts of coating or none at all. A coated caveola suggestive of micropinocytotic activity is evident in the plasmalemma of the terminal toward the left.

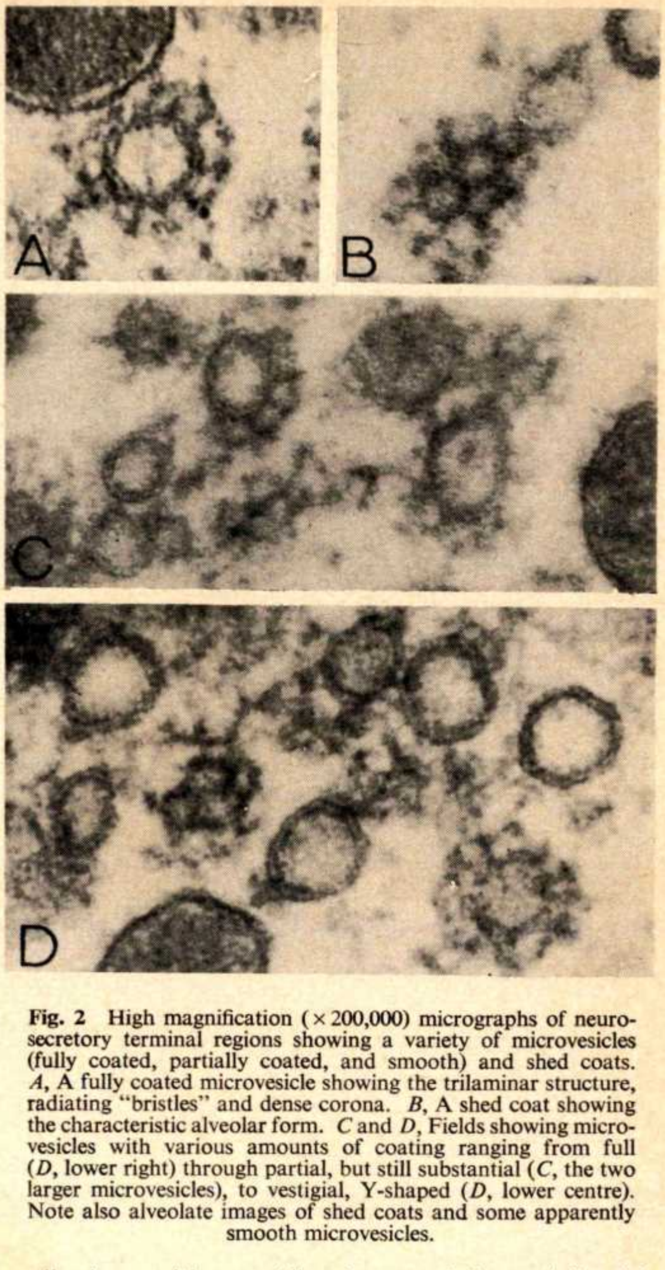

Fig. 2 High magnification (× 200,000) micrographs of neurosecretory terminal regions showing a variety of microvesicles (fully coated, partially coated, and smooth) and shed coats. *A*, A fully coated microvesicle showing the trilaminar structure, radiating "bristles" and dense corona. *B*, A shed coat showing the characteristic alveolar form. *C* and *D*, Fields showing microvesicles with various amounts of coating ranging from full (*D*, lower right) through partial, but still substantial (*C*, the two larger microvesicles), to vestigial, Y-shaped (*D*, lower centre). Note also alveolate images of shed coats and some apparently smooth microvesicles.

The appearance of the fully coated vesicle at higher magnification (Fig. 2*A*) conforms to the pattern found in other tissues[5]: a trilaminar vesicle resembling the smooth "synaptic" vesicle except for an investment of rather geometrical appearance suggestive of the spokes of a wheel or a corona of radiating bristles, commonly about ten in number, whose apices are joined and interstices filled by fainter electron densities. From their analysis of corresponding images from conventional neurones Kanaseki and Kadota[5] suggested they result from the superimposition of the walls of a honeycomb structure (or "basket") investing the vesicle.

Examples of partially coated and smooth vesicles at equally high magnification are presented in Fig. 2*C* and *D*. Scattered among them are faint alveolate figures in which no vesicle can be discerned. These were abundant in our material and with practice easily recognized. Their appearance, in favourable sections (Fig. 2*B*), corresponds closely with that depicted by Kanaseki and Kadota[5] and, following these authors, we take them to be shed coats. The model of the coated vesicle constructed by Kanaseki and Kadota has a surface composed of twelve pentagons and twenty hexagons. It follows that the figure depicted in Fig. 2*B*, with about ten alveolae, represents a large area of coating. Shedding of such large pieces would result in partially-coated vesicles with extensive denuded areas, but coating could be shed in smaller or larger pieces. Still greater loss of coating, by whatever means, seems likely to account for vesicles with only a few spokes or bristles (Fig. 2*D*, centre), and shedding of these vestiges would yield smooth vesicles. The sequence explains how smooth "synaptic" vesicles, devoid of the coating stigmatic of membrane vesiculation[4,5], can yet be of micropinocytotic origin.

Although coated vesicles are abundant in our material, it is understandable that they have hitherto received so little attention[2] in this much studied gland, for coats are not prominent without special staining such as uranyl extraction in block, and when reduced to a few spikes are inconspicuous although often recognizable by characteristic thorn shapes or Y shapes (Fig. 2*D*, centre). Moreover, the relative abundance of coated forms in glands fixed during stimulation suggests they are short-lived and refractory to capture by conventional methods.

The presence of so many coated vesicles in glands fixed during stimulation considered along with the evidence they shed their coats to become smooth "synaptic" vesicles, greatly strengthens our hypothesis on the micropinocytotic origin of these long-enigmatic structures. Further support of a quite different sort is provided in the following companion report (see next communication[7]).

Micropinocytotic Origin of Coated and Smooth Microvesicles ("Synaptic Vesicles") in Neurosecretory Terminals of Posterior Pituitary Glands demonstrated by Incorporation of Horseradish Peroxidase

ELECTRON microscopic evidence[1-3] has led us to believe that smooth microvesicles ("synaptic vesicles") within neurosecretory terminals of posterior pituitary glands arise from coated microvesicles formed by invagination and vesiculation of the cell surface following exocytosis (see preceding communication)[3].

This view implies that microvesicles of both sorts have been open, at some time, to the extracellular environment, and it should be possible to test this by determining whether they engulf marker substances that do not traverse the intact cell membrane. One such substance, horseradish peroxidase, has been used more than any other to demonstrate micropinocytosis in various cells[4-6]. We here report the presence of horseradish peroxidase in both coated and smooth "synaptic" microvesicles of neurohypophyseal terminals of rats and hamsters (the species in which exocytosis has been demonstrated[1,2]) after injecting this substance intravenously or introducing it to isolated glands incubated with excess K to induce secretion[7].

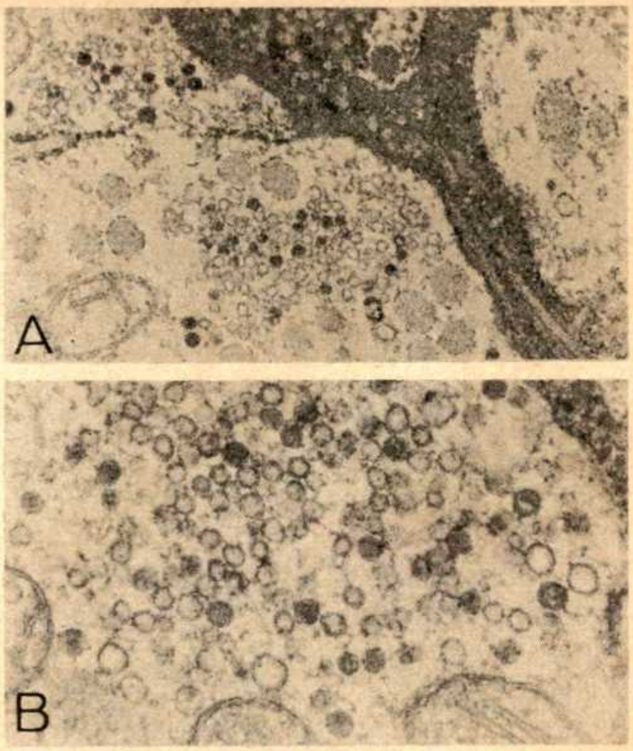

Fig. 1 Incorporation of horseradish peroxidase (HRP) into microvesicles within neurosecretory terminals of posterior pituitary glands of hamster and rat. *A*, Hamster (♂, 90 g), urethane anaesthesia (0.3 ml., 33% w/v given intraperitoneally). HRP 100 mg in 1 ml. Locke by jugular vein. Animal decapitated 10 min later and posterior pituitary fixed with a mixture of glutaraldehyde (3.4%) and paraformaldehyde (1%) in cacodylate buffer and processed for demonstration of HRP according to Karnovsky[4]. Note electron-dense reaction product indicative of HRP is present in numerous microvesicles as well as perineuronal spaces (× 38,000). *B*, Rat (♂, 190 g), unanaesthetized. The posterior pituitary was removed after decapitation and incubated in "high K Locke's solution"[7] containing HRP (100 mg/ml.) for 15 min at 37° C. Many microvesicles contain electron-dense reaction product (× 60,000).

The presence of horseradish peroxidase in many members of the microvesicle population in the two species is illustrated in Fig. 1 where the electron density of the reaction product has rendered these vesicles dark. No reaction product was found in microvesicles in control experiments where horseradish peroxidase was omitted. High power micrographs show most of the labelled microvesicles are smooth "synaptic vesicles" (Fig. 2*E*), but others are coated (Fig. 2*A*–*D*). As noted before[2], the coated vesicles commonly lie close under the plasmalemma in association with coated caveolae. This, taken together with the incorporation of horseradish peroxidase, leaves little doubt they are the immediate product of membrane vesiculation. The presence of horseradish peroxidase in smooth microvesicles establishes that they too are of micropinocytotic origin. But they are unlikely to arise directly by plasmalemmal vesiculation since coating is believed to be essential for the membrane buckling inducing vesiculation[8,9] and no caveolae were observed without coating in these or previous experiments[3] employing uranyl extraction which renders coats readily visible. The smooth vesicles more probably arise from the coated forms by the shedding of coats described in the preceding report[3].

With the micropinocytotic origin of many coated and smooth microvesicles now established, there remain two important questions. First: do all microvesicles in neurohypophyseal terminals arise in this way? This is feasible, for each exocytotic event involving one neurosecretory granule would require formation of some ten to twenty-five microvesicles if the cell surface is not to expand[1,2]. Failure to detect reaction product

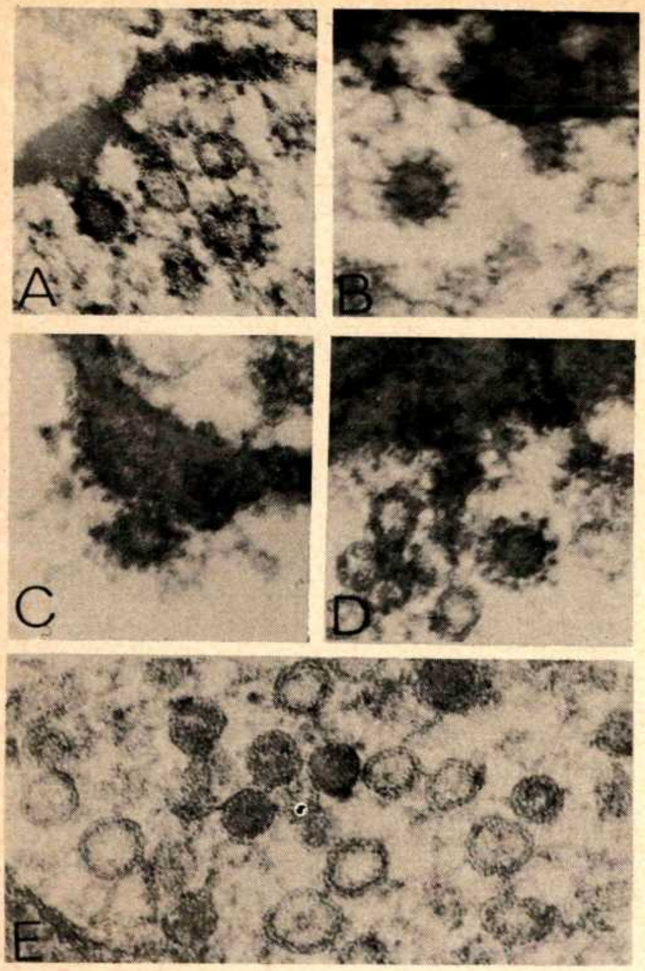

Fig. 2 Terminal portions of neurosecretory fibres showing evidence of micropinocytosis; coated caveolae and adjacent coated microvesicles containing horseradish peroxidase (HRP). (All × 128,000.) *A* and *B*, Hamsters. Pituitaries were removed and fixed 5 min after HRP (100 mg) had been given intravenously. Note coated caveolae in plasmalemma in both, and, in *B*, a coated microvesicle containing reaction product. *C* and *D*, Rats. Pituitaries were incubated *in vitro* (15 and 2.5 min respectively) in high K Locke containing HRP (100 mg/ml.). In *D*, a caveolus and adjacent coated microvesicle is filled with reaction product. In *C*, a coated microvesicle filled with reaction product lies close under a coated depression in the plasmalemma. This may correspond with the images previously interpreted[1,2] as micropinocytosis occurring within an exocytotic pit. *E*, Horseradish peroxidase in smooth microvesicles of the classical "synaptic vesicle" type. Same preparation as 1*B* but higher magnification (× 128,000).

in many microvesicles does not necessarily mean their origin is different: some were probably present before horseradish peroxidase was introduced, and others could have formed without admitting this bulky molecule; moreover, it is unlikely that histochemical detection is 100% efficient. Nevertheless, it is evident that alternative suggestions[10,11] concerning the origin and significance of microvesicles could still apply to some of the population.

The second question concerns the fate of the microvesicles. To this we can only repeat our previous conjecture that they are disposed of somehow, possibly by lysosomes[2]. They are not likely to be re-used for packaging of hormone since this takes place in the distant perikarya and not in the neurosecretory terminals[12]. But, as we pointed out at a symposium in Bristol last year[2], a similar tightly coupled exocytosis–micropinocytosis sequence could be of functional significance in ordinary nerve endings where local synthesis and packaging (of neurohumour) do occur[13] and allow for recycling of true synaptic vesicles. Support for this conjecture has since been provided by Gray and Willis[14] who, like us[3], have been inspired by Kanaseki and Kadota's work[9] and have obtained evidence, in ordinary nerves, that coated vesicles, probably of micropinocytotic origin, can give rise to smooth synaptic vesicles. But clearly our "recycling" hypothesis could only apply if neurohumours, like the neurohormones, are released by exocytosis. Electron microscopy has left this question unanswered since in ordinary nerve endings the caveolae, devoid of electron-dense material, could as well represent micropinocytosis as exocytosis[6]. Nevertheless, some electrophysiological[15] and biochemical[13] evidence favours exocytosis, and from ontogenetic and ionic parallels it has been argued that secretory mechanisms in ordinary neurones and neurosecretory fibres are probably similar[16].

Changes in ATP and Creatine Phosphate Storage in Skeletal Muscle of Rats trained at 900 and 7,600 Feet

THE hydrolysis of ATP provides the energy source for muscular contraction. ATP is either stored in the muscle or produced by phosphorylation of ADP by creatine phosphate or glycolytic processes, or through oxidative processes in the mitochondria. The processes of adaptation which facilitate the glycolytic or oxidative production of ATP have been studied in trained and acutely exercised animals. After work has been done by the muscle, the oxidative[1] and glycolytic[2,3] capacities of its fibres increase. Christensen[4] has shown that neither glycolysis nor oxidative processes take place during short anaerobic bursts of activity. The energy for such limited activities is provided by the hydrolysis of stored ATP and phosphorylation of ADP by creatine phosphate by the Lohman reaction. Previous exercise studies using endurance types of training have not shown any adaptation of either ATP or creatine phosphate[5–7], although electrical stimulation[8] and dwelling at high altitude[9] have produced increases in creatine phosphate.

Seventy Sprague-Dawley albino rats, 35 days old, were tested for their ability to run on a motor driven treadmill. Fifty-four animals were selected and placed into six groups of nine rats each. Three groups, sedentary, sprint trained and endurance trained, each lived in large dormitory cages, 28 inches by 13 inches by 8 inches, kept in ambient conditions

900 feet above sea level. Three other groups were housed in altitude cages of equal dimensions. These cages were maintained at a simulated altitude of 7,600 feet. The sprint and endurance trained rats at simulated altitude ran on a treadmill housed in a hypoxic atmosphere at ambient pressures, such that the inhaled oxygen pressure was equivalent to that at 7,600 feet. All the groups were maintained for 63 days.

Endurance trained animals were run with progressively increased work loads until they were running for 30 min at an average speed of 34 m min^{-1} and 30 m min^{-1} in the ambient and altitude conditions respectively. Throughout the training period the altitude endurance group ran at about 88% of the ambient group's speed. Sprint trained rats were all run at identical speeds regardless of the altitude condition. These rats were run for six to eight intervals of 15 s each with 1 min of rest between each interval. For the final 3 weeks of the study all rats ran at 81.1 m min^{-1}. The rats were run daily; they were run six days per week, beginning with the thirty-fifth day.

At the completion of the training period the rats were anaesthetized with sodium pentobarbitol, and the gastrocnemius–plantaris (as one unit) and the soleus were removed. The muscles were immediately frozen in isopentane chilled to liquid nitrogen temperature. All of the muscles were pulverized in a cold room, deproteinized in cold perchloric acid (30 ml./0.5 g frozen tissue) and analysed for ATP and creatine phosphate[10]. Data were analysed using a two-way analysis of variance for groups with uneven *n* values[11]. The Scheffe *post hoc* test[12] was used to determine significant differences between means.

Table 1 Molar Quantities of Measured Phosphate Compounds of the Soleus

	ATP	Creatine phosphate
Ambient control $N=8$	2.48	6.50
Ambient sprint $N=9$	2.15	5.03
Ambient endurance $N=4$	2.61	7.18
Altitude control $N=9$	2.28	6.28
Altitude sprint $N=7$	2.58	6.04
Altitude endurance $N=8$	2.20	5.99

Quantities in μmol/g of tissue (wet).

Table 2 Molar Quantities of Measured Phosphate Compounds of Gastrocnemius–Plantaris

	ATP	Creatine phosphate
Ambient control $N=8$	3.13±0.638	7.89±0.589
Ambient sprint $N=9$	3.77±0.754	8.60±2.104*
Ambient endurance $N=3$	3.45±1.006	7.49±1.966
Altitude control $N=9$	3.51±0.484	8.59±1.561
Altitude sprint $N=7$	3.68±0.711	10.82±1.876†
Altitude endurance $N=8$	3.64±1.136	8.78±1.965‡

Quantities in μmol/g of tissue (wet) ±s.d.

* Greater than ambient endurance ($P<0.05$).

† Greater than all other groups ($P<0.05$).

‡ Greater than ambient endurance ($P<0.05$).

Table 1 summarizes the results of the biochemical analyses of the soleus. Because of the muscle's small size all the soleus from each group was analysed as one sample and no statistical analyses were performed. There was little difference in the quantities of ATP or creatine phosphate between the groups. Table 2 summarizes the values for the gastrocnemius-plantaris. ATP values were not affected by either training or altitude ($P>0.05$). Sprint training affected creatine phosphate stores. The ambient sprint group had more creatine phosphate than the ambient endurance group ($P<0.05$). The altitude sprint group had more creatine phosphate than either the altitude control or endurance groups and also more than the ambient sprint group ($P<0.05$). Although the two control groups were not different ($P>0.05$), both of the altitude activity groups had greater quantities of creatine phosphate than their respective ambient counterparts. All of the gastrocnemius-plantaris values exceeded those of the soleus.

Changes in the storage of creatine phosphate did occur as a result of sprint training in the gastrocnemius-plantaris muscles which have a large area of white fibres[13,14]. Although the low altitude alone had no effect, the increase in creatine phosphate was potentiated by altitude for the running groups. This would suggest that even at 7,600 feet there is a hypoxaemic state which is greater than that even in the sprinting muscle at sea level.

The difference between the soleus and the gastrocnemius–plantaris would be the expected relationship between red and white muscle, red muscle being lower in the high energy phosphates. The fact that the quantities in the soleus were not affected by sprinting would suggest that red muscle is not used during this type of activity. Some fibres of the gastrocnemius–plantaris, however, were affected by endurance running at altitude. It remains to be seen whether the fibres which increased their creatine phosphate stores as a result of altitude endurance training were red, white or intermediate. It is assumed that the white fibres did adapt to short, anaerobic stresses by increasing the quantities of creatine phosphate available for phosphorylation of ADP.

Fertilization of Denuded Rabbit Eggs *in vitro* by Sperm recovered from the Uterus or Vagina

RECENTLY shed eggs, are surrounded by a sticky mass of follicular cells known as the cumulus oophorus. The follicular cells, which are closely attached to the zona pellucida and are arranged in a compact radial pattern, are called the corona radiata. It has been postulated that the follicular cells in the cumulus oophorus can protect the egg against polyspermic fertilization, and can improve the chance of fertilization by providing a large target for the sperm. Further, due to the radial arrangement of the corona radiata, these follicular cells can act in orientating the sperm towards eggs[1]. After the dissolution of cumulus oophorus by treatment with hyaluronidase *in vitro*, however, rabbit eggs can be fertilized when transferred into the tubes of mated rabbits[2,3]. After the dissolution of cumulus oophorus and removal of the corona radiata by manual shaking, the denuded eggs can also be fertilized *in vitro*[4] or *in vivo*[5,6]. A comparison of the proportion of eggs fertilized *in vitro* between denuded eggs and those with follicular cells intact has not been made. In addition, it has been speculated that the progesterone present in the follicular fluid or synthesized by the granulosa cells may be necessary for the "acrosome reaction", capacitation of sperm, and the fertilization of eggs *in vitro*[7]. The experiment described here demonstrates (1) that denuded rabbit eggs lacking follicular cells (or progesterone) can be fertilized equally as well as intact eggs with cumulus oophorus, and (2) that sperm recovered from the vagina can fertilize rabbit eggs *in vitro* as well as those recovered from the uterus.

Table 1 Fertilization of Denuded Rabbit Eggs *in vitro* by Sperm recovered from the Uterus or the Vagina

Collection site and No. of sperm (millions/ml.)	Denuded eggs			Eggs with follicular cells intact		
	Total	No. fertilized	Percentage fertilized	Total	No. fertilized	Percentage fertilized
Uterus (0.06–0.17)	48	16	33	92	27	29
Vagina (0.23–4.2)	45	24	53	30	14	47
Ejaculate (0.97–5.1)	41	0	0	32	0	0

Mature female rabbits were injected either subcutaneously or intramuscularly with 170 IU of PMS to induce growth of a large number of follicles and 72 h later they were injected intravenously with 90 IU of HCG to induce ovulation. Approximately 15 h after injection of HCG the Fallopian tubes were removed and flushed with a tissue culture medium (TC 199) to recover the eggs. Immediately after recovery, one group of eggs in the mucous clot was placed in a watch glass containing 0.5 ml. of 0.1% hyaluronidase in TC 199 and the other group was placed in another dish containing no hyaluronidase. After the dissolution of the cumulus (about 10 min), the hyaluronidase-treated eggs were placed in a small test tube (4 cm long) and denuded by being shaken vigorously by hand for about 5 min. The denuded eggs were then placed in another dish containing TC 199. The procedures for fertilizing rabbit eggs are essentially similar to those reported previously[8].

For the recovery of capacitated sperm, one female was mated consecutively by three fertile bucks. It was anaesthetized with nembutal 14–18 h after mating. After making a medial incision the uterine horn or vagina was flushed with 2–3 ml. of a freshly prepared medium[9]. About 1 ml. of uterine or vaginal washing (containing strongly motile sperm) was placed in a 1.5 ml. Carrel flask. The denuded eggs were placed into one flask prepared in this way, and the intact eggs with cumulus clot were placed into another. The flasks were closed with a rubber bulb and attached to a gentle rocking device in an incubator at 38° C. After 3–4 h the eggs were picked up and subcultured in a 6 ml. capacity Carrel flask containing 4 ml. of TC 199 incorporating 20% heated rabbit serum. After incubation for another 18–20 h, the eggs were taken out, mounted on a slide and examined. They were then fixed with neutral formalin, stained for the assessment of fertilization[2,8], and examined again. Usually a second maturation chromosome pattern or a group of small nuclei can be seen in the unfertilized eggs. Most of the fertilized eggs are at the four-cell stage. Fragmentation of fertilized and especially unfertilized eggs is fairly common.

The results presented in Table 1 indicate that there is no difference in the proportion of eggs fertilized *in vitro* whether the eggs are denuded or not. The presence of follicular cells (or progesterone) does not appear to play a role, therefore, for the fertilization of rabbit eggs *in vitro*. We have also discovered that the proportion of eggs fertilized by vaginal sperm is significantly higher than by uterine sperm. Whether this is due to a higher concentration of sperm or better vitality of sperm in the vaginal washing is still to be determined.

Role of Skin and Neurohypophyseal Hormones in the Adaptation of the Toad *Bufo viridis* to High Salinities

Many people maintain that ADH is important in the control of water and salt metabolism of amphibia[1]. The toad *Bufo viridis* is one of the species most resistant to dehydration and high ambient salinity, in which situations it has a high plasma salt concentration. In toads adapted to high salinity, the urine sodium chloride concentration increases to about plasma level, whereas active sodium transport, as measured by short circuit current, is almost completely reduced (ref. 2 and our measurements). The animals apparently do not drink and water is passively transferred along the osmotic gradient from the ambient solution into the body. We found that the sensitivity to added hormone was lost from the skins of animals that were adapted to saline solutions above 400 mosm.

We studied the water flux across isolated portions of skin in saline-adapted animals. The skin was carefully dissected and attached to a 'Perspex' conus, the inside facing out, and the preparation was maintained in aerated Ringer solution (NaCl 120 mmol l.$^{-1}$; KCl 2.5 mmol l.$^{-1}$; $CaCl_2$ 2 mmol l.$^{-1}$ at $pH=8$). The inner solution was hypotonic, and water transfer was followed gravimetrically on a 0.1 mg precision Metler balance. The temperature was maintained at 20° ± 1° C. A typical experiment is shown in Fig. 1. When skin was used from animals adapted to high saline, osmotic equilibrium was adjusted with sodium chloride. Synthetic oxytocin ('Syntocinon', Sandoz) was used throughout.

Skin from toads kept in either tap water of 230 mosm solution (containing either sodium chloride or sucrose) was almost impermeable to water; the application of hormone to the external bath (serosal side) stimulated the water flux across the skin. When skin from toads adapted to 400 mosm NaCl solution was tested, water flux occurred as soon as there was a gradient across the skin; the application of hormone to the external bath did not have any further effect.

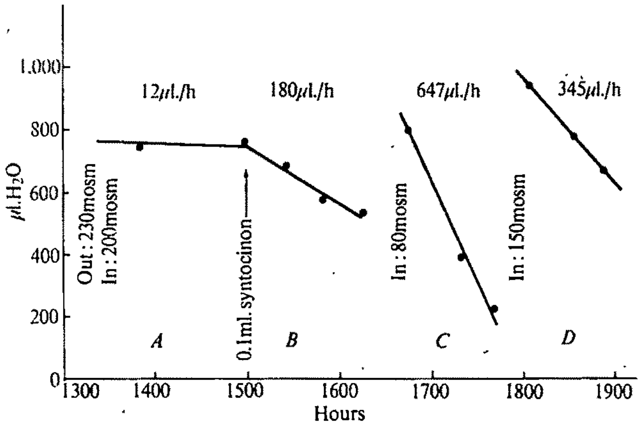

Fig. 1 Results of a typical experiment of the *in vitro* method to follow water flux across the isolated skin. In the first period (*A*) an osmotic gradient was imposed across the skin, with its inside facing outwards. At the arrow, hormone was added to the external medium and weight change followed. In the two successive periods (*C*, *D*) different gradients were imposed. The rate of water flux for each period is indicated above.

Although the solutions used in the latter case were hypertonic to normal Ringer of amphibia, they were definitely not hypertonic to the preparations being studied, which were always in osmotic equilibrium. To check this, however, we tested skin from normal animals in hypertonic solution and skin from 500 mosm NaCl-adapted animals in hypotonic solution. An effect similar to that of ADH was observed in the first case, which was similar to observations[3] on frog urinary bladder. In the second case, the change of the solution did not change the properties of the skin, and water transfer ensued without the addition of hormone.

In animals adapted to 400 mosm NaCl and then brought back to tap water through 230 mosm NaCl, the effect was reversible in that the responsiveness of the skin to the hormone was restored.

The increased permeability of the skin to water, which is maintained without the addition of hormone, seems to be very important to the water metabolism of the toad. To ascertain the amount of hormone in the circulation, we used the *in vitro* assay[4] of hormone on isolated normal bladders. Blood collected from three or four animals was pooled, centrifuged in the cold, and 2 ml. of the plasma was added to 10 ml. of the external solution. No response was observed with plasma from animals that were maintained in either tap water, 230 mosm or 450 mosm NaCl. Hydro-osmotic activity was found, however, in the plasma of animals dehydrated in 2.5% NaCl for 3 h (ref. 5). In another series of experiments the hormonal activity of the hypophysis was investigated semi-quantitatively by using the *in vitro* method with the addition of neurohypophyseal extract. The results showed the existence of almost the same activity in the animals from either tap water, 230 mosm NaCl or 400 mosm NaCl solutions.

It seems that adaptation to high salinity in these toads leads to some fundamental physiological changes in the skin. It is of interest to mention that Dicker and Elliott[6] working on *Rana crancrivora*, a euryhaline species inhabiting brackish mangrove swamps, also found an apparent lack of hydro-osmotic response to neurohypophyseal peptides in the isolated bladder.

We are at present investigating whether the changes in the skin that we found are also reflected at the ultrastructural level.

Sterilization of *Aedes aegypti* (L.) as a Result of Chronic Exposure to Low Doses of Beta Radiation

THE application of the sterile male technique for the control of insect populations depends on the release of an adequate number of sterilized males. Whitten and Taylor[1] have suggested that the effectiveness of the method might be enhanced by releasing sterile females along with the sterilized males. In the case of mosquitoes, however, any addition to the number of biting females already present in a native population would be unwelcome.

So far efforts to use the sterilized insect for mosquito population control have generally involved insects that were irradiated during pupal or adult stages. We have succeeded in sterilizing more than 70% of the adults of laboratory populations of *Aedes aegypti* (L.) by exposing them to a total dose of beta radiation estimated to be as small as 90 rad during the early larval stages. This dose is about one-tenth of the X-ray doses which have been used to sterilize the pupal or adult stages[2]. Willard[3] has studied the long term effects of acute X-ray irradiation of the egg, larval and pupal stages of *A. aegypti*, on the population dynamics of that species.

If sterilized males and females are to be used for mosquito population control, it is important that a significant number of viable eggs is not laid as a result of their mating. Twelve groups of 100 newly hatched *A. aegypti* larvae were irradiated for 192 h during instars I to IV, by rearing them at 24±1° C in media containing 0.1, 1.0 and 10 μCi/ml. ^{90}Sr in equilibrium with its daughter product ^{90}Y. The amounts of ^{90}Sr and ^{90}Y accumulated by the larvae were quite variable, so it was not feasible to calculate the dose delivered. The use of sealed $^{90}\mathrm{Sr}+{}^{90}\mathrm{Y}$ plaques placed in the rearing medium will deliver only an external dose which can be calculated. Controls were exposed to natural background radiation only. Hatching and rearing methods were essentially those described by Riordan[4]. After 192 h, instar IV larvae were removed from the radioactive media, rinsed and placed in demineralized water to pupate. The adults were allowed to mate. Males were offered a 50% solution of honey in water. Females were also allowed to feed on guinea-pigs. Blood-feeding from guinea-pigs, and egg laying were observed. The effects on egg laying of mating irradiated males with non-irradiated females, and *vice versa*, were not examined in these experiments.

Larvae reared in 10 μCi ^{90}Sr/ml. did not pupate, while those reared in 0.1 and 1.0 μCi/ml. developed normally and the adults had no gross external morphological abnormalities. The development of the ovaries and the testes, however, had been arrested.

Table 1 Effect of Continuous Beta Irradiation of Instar I to IV Larvae on Feeding and Egg Viability of Adult *A. aegypti*

^{90}Sr concentration (μCi/ml.)	Males		Females	
	Took honey-water	Took blood meal	Laid eggs	Viability of eggs laid
Background	Yes	Yes	Yes	80%
0.1	Yes	Yes	No	—
1.0	—†	No	No	—
10.0*	—	—	—	—

* Larvae failed to pupate and died 25 days after moulting to instar IV.

† Not observed.

Feeding and egg laying are summarized in Table 1. All females were dissected 10 days after those in control groups laid eggs, or when they became moribund. Females irradiated as larvae laid no eggs. In addition, females in the 1.0 μCi ^{90}Sr/ml. treatment groups took no blood. Dissection showed that most of the radiation-treated females had motile sperm in their spermathecae, but their ovaries were atrophied. According to Bugher and Taylor[5], failure to produce eggs is the first indication of abnormality caused by increasing radiation dose. Leahy and Craig[6] have reported an accessory gland substance, transmitted from the male to the female during copulation, to be a stimulant for oviposition in *A. aegypti* and *A. albopictus*. The irradiated females in our experiments may not have received this substance. Smittle[7], studying the effects of gamma radiation on *Culex pipiens quinquefasciatus*, suggested that sterilization of the females was the result of inhibition of egg production. Although some of the irradiated females in our experiments took blood (Table 1), their ovaries were atrophied, and therefore eggs could not be produced.

Our observations, that females reared in 1.0 μCi ^{90}Sr/ml. took no blood meals and laid no eggs, suggest that sterile females might usefully be used in combination with sterile males to control mosquito populations. The production of large numbers of larvae[8], irradiated externally by means of sealed beta sources, would not be difficult. Investigations of the effects of chronic external beta and gamma radiation on mosquito populations are in progress.

Transmission of *Phytophthora* Pod Rot of Cocoa by Invertebrates

Phytophthora palmivora (Butl.) Butl., the causal agent of black pod of cocoa (*Theobroma cacao* L.), accounts for an estimated 19% crop loss in Ghana[1], and losses are considerably higher in wetter countries such as Nigeria and the Cameroun Republic. The epidemiology of the disease is still uncertain but rain-splash from soil is considered by some workers[2,3] to trigger-off disease cycles.

During a study of 200 mature cocoa trees, black pod lesions were consistently associated with pods colonized by tent building ants. These tents serve as shelters for coccids (scale insects) which usually feed on the pod peduncle. The coccids are tended by ants which remove excess sugars for their own use. An extensive survey of black pod–ant tent relationships has been undertaken and five stands of mature cocoa trees, comprising ant-free and ant-colonized trees, have been selected for comparative studies. Preliminary results indicate a positive correlation between certain tent building ant species and the levels of black pod. The type of material used in the construction of the tents is the most important factor involved. For this reason ants of the genus *Crematogaster*, and specifically *C. striatula* Emery, appear to be the most important vectors of black pod. These ants remove the outer layers of healthy and diseased pods and use the material to construct tents and other temporary shelters. *C. striatula* in well shaded cocoa can assume complete dominance over wide areas. Black pods left on the ground after harvesting or left hanging on the tree are used as building material and small discrete tents are constructed primarily around the pod peduncle. The ants are, therefore, effectively transferring infected pod material from the ground or from on the tree sources to healthy pods. Ants moving from the base of the tree upwards have been trapped and in several cases material containing spores of *P. palmivora* was being carried for use in tent construction. *C. africana*, *C. clariventris* and *C. depressa*, in addition to *C. striatula*, have all been observed scraping and carrying away material from black pods left hanging on the tree or lying on the ground.

Other ant species seem to be more incidental in the spread of black pod as they rarely use diseased pod material in tent construction. *Camponotus acvapimensis* builds very large tents composed almost entirely of soil. Soil infested with spores of *P. palmivora* may be carried to healthy pods in "soil balls" and ultimately cause infection. *Pheidole* spp., mainly *P. megacephala*, and *Acantholepis capensis* also build large soil tents, although almost any freely available material may be included. The importance of these ants in the dissemination of black pod will depend very much on the amount of viable soil inoculum present in a particular area.

Tent building ant species, therefore, may be important vectors of black pod causing local epiphytotics. In particular, it is thought that *C. striatula* because of its building habits and its complete dominance under certain conditions may be responsible for serious black pod losses. The soil-tent ant species, although less directly involved in the dissemination of diseased material, may initiate disease outbreaks by carrying inoculum in soil to healthy pods and creating primary infection foci; secondary spread by rain-splash may follow. The proportion of cocoa trees colonized by tent building ants may be very high[4] and their significance in the vertical spread of black pod should not be overlooked.

It is considered that ants are responsible primarily for vertical disease transmission, but horizontal spread may be attributable to other invertebrate vectors. Thorold[5] noted the absence of infection gradients in the field and concluded that horizontal dispersion of black pod follows a random pattern of the type expected for an airborne disease. Nevertheless, sporangia of *P. palmivora* have never been isolated from the air[6,7] and horizontal spread is still speculative and largely unexplained. Microscopic examination of faeces of herbivorous invertebrates commonly found on black pod revealed the presence of *P. palmivora* spores. Faecal material, wound-inoculated into healthy pods, produced typical black pod lesions. Viable spores have now been recorded from the faeces of eight beetle species, three millipede species, four caterpillar species and four snail (slug) species. Beetles are by far the most prevalent invertebrates on black pods and one species in particular (family *Nitidulidae*) occurs on 50–60% of black pods. The invertebrates feed on the outer tissues of black pods and in the process ingest mycelium and spores of *P. palmivora*. These remain intact during passage through the gut and are ejected together with cutin, pod hairs and stomatal guard cells. An extremely high percentage of the sporangia pass through the alimentary tracts of snails, millipedes and caterpillars without damage and pod inoculations from these faeces invariably cause infection. Most sporangia in beetle faeces are devoid of contents and infectivity is low. It is thought that at a certain stage in development the sporangial papilla becomes susceptible to enzyme attack and the sporangial contents are digested by the insect. Chlamydospores seem to remain unchanged after ingestion by invertebrates.

Flying insects, carrying inoculum of *P. palmivora* in the faeces, may explain the random occurrence and "over-dispersion" of black pod recorded by Thorold[5,8] which led him to suggest air dispersal as a means of dissemination. The importance of the other invertebrates in the transmission of black pod is difficult to assess. But the widespread occurrence of these animals in cocoa farms implies that they may be responsible for some horizontal spread. By feeding on black pods left on the ground after harvesting they may move around large amounts of inoculum, possibly introducing spores in previously disease free soil from where they may be dispersed by ants or rain-splash.

The answer to black pod control may lie partly in the efficient application of insecticides and Weststeijn[9] noted that the addition of a DDT-formulation to lime Bordeaux mixture distinctly improved the control of black pod. The effective removal of diseased pods from the cocoa farm after harvesting is an obvious control method, thereby limiting the amount of infective material available to tent-building ants and herbivorous invertebrates. This preliminary evidence of the transmission of black pod by invertebrates may partly explain the vertical and horizontal spread of this economically important pathogen.

I would like to thank Mr B. Bolton for initial identification of the ant species. I am a member of the British Research Team of the British Overseas Development Administration.

Metabolic Implications of Polymorphism as an Adaptive Strategy

ENZYME polymorphisms are known to be widespread in natural populations[1–3]. No adequate theory has been advanced to account for their frequent occurrence; some workers support the proposition that they are selectively "neutral"[4–6], while others present evidence that they are maintained in natural populations through natural selection rather than by non-selective processes[1,7–9].

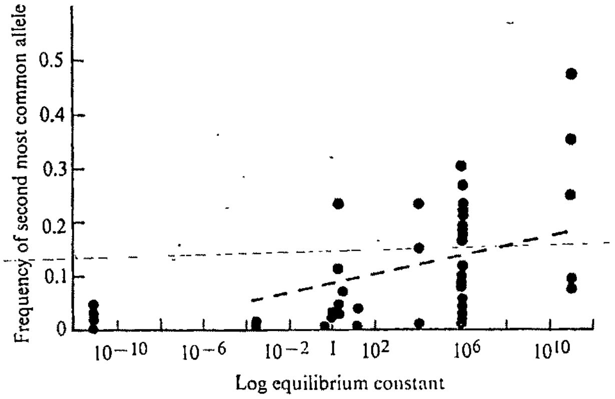

Fig. 1 Relationship of polymorph frequencies to equilibrium constant. For each of fourteen enzymes, the reported frequency of the second most common allele for a given population is plotted as a function of the corresponding equilibrium constant. The coefficient of correlation for a linear regression analysis of these data is 0.483, significant at the 0.1% level. Non-specific enzymes were not analysed. $Fn4 = 27.08$, $P \ll 0.005$.

The hypothesis that selection acts to maintain enzyme polymorphisms in natural populations has important metabolic implications not previously considered. Within any metabolic pathway a given catalyst will affect the rate of end-product formation according to its role in the kinetics of the overall sequence; those enzymes which exert acute control over flow through the pathway (that is, irreversible and rate-limiting steps) should be most individually sensitive as sites of action of selective forces (in contrast to selection on generalised metabolic systems[10]). Thus if natural selection affects the output of metabolic pathways by modulating the extent of molecular heterogeneity among the enzymes of the pathway, such selection should be most efficient if applied at those metabolic steps which most specifically control flow through the pathway.

The results of applying selection to enzymes with different kinetic roles in metabolism can be seen most clearly in irreversible reactions. In a freely reversible reaction, mass action must strongly dilute the effect of any change in the kinetics of the reaction on previous or subsequent reactions. An irreversible reaction may act by mass action to promote the operation of the pathway both proximal and distal to it, previous reactions being drawn along by its removal of substrate, and subsequent reactions being driven by its products; thus the activity of an enzyme catalysing an irreversible reaction has effects extending over the whole pathway. The action of selection in maintaining a natural, stable enzyme polymorphism would be enhanced if applied to such an "acute control" point, as it would critically affect the efficient operation of the entire metabolic sequence.

Table 1 Enzyme Polymorphism in *Drosophila*

Enzyme	K_{eq}	Sample size	Populations significantly polymorphic (%)	Index of polymorphism
Alcohol dehydrogenase (1.1.1.1)	1×10^{11} (19)	1,150	100	0.330
Aldehyde oxidase (1.2.3.1)	2×10^{6} (20)	850	66	0.120
Xanthine dehydrogenase (1.2.3.2)	Very large (21)	703	66	0.131
α-Glycerophosphate dehydrogenase (1.1.99.5)	1×10^{4} (12)	831	40	0.083
Glucose-6-phosphate dehydrogenase (1.1.1.49)	3×10^{2} (20)	527	28	0.054
Hexokinase (2.7.1.1)	155 (23)	141	50	0.007
Isocitrate dehydrogenase (1.1.1.41)	20 (20)	743	40	0.029
Malic enzyme (1.1.1.40)	20 (24)	687	20	0.012
Phosphoglucomutase (2.7.5.1)	17 (25)	464	75	0.137
Fumarase (4.2.1.2)	4 (26)	577	0	0.013
6-Phosphogluconate dehydrogenase (1.1.1.44)	1 (27)	187	0	0
Phosphohexose isomerase (5.3.1.9)	0.3 (28)	251	0	0.002
Aldolase (4.1.2.13)	2×10^{-4} (29)	515	0	0.006
Malate dehydrogenase (1.1.1.37)	7×10^{-13} (20)	1,012	10	0.015

Reported values of the equilibrium constants of the fourteen enzymes are listed; for enzymes with variation in reported values, the value closest to 1.0 was chosen. In all cases, the physiological direction of the reaction in insects was used in determining the equilibrium constant. Also listed for each enzyme is the sample size, *n* (the total number of individuals from all populations examined for a given enzyme), the percentage of the populations examined in which high frequency polymorphisms (two or more alleles with frequencies $\geq 4\%$) are reported, and the index of polymorphism $(1-P)$.

These metabolic considerations predict that if enzyme polymorphisms are maintained in natural populations by selective forces, a survey of the occurrence of polymorphisms in various enzymes of individuals of natural populations would reveal a greater degree of polymorphism in enzymes catalysing physiologically irreversible reactions; significantly less polymorphism would be expected for enzymes whose reactions are freely reversible, or possess equilibria strongly favouring the reverse of the physiologically significant direction.

Unfortunately, most surveys of enzyme polymorphism reported so far cannot adequately test this hypothesis, as they have been conducted on very small samples of natural populations[1,11–13]. Investigations of inbred laboratory strains[14] are unsatisfactory for this purpose as the selective advantage of polymorphisms in such strains is less clear. Within the past few months, however, extensive surveys of major metabolic enzymes in natural populations of numerous species of *Drosophila* have been reported[15–17], which allow a meaningful test of the hypothesis outlined here.

Table 1 is a compilation of these studies; the frequencies of polymorphism for as many as fourteen enzymes in individuals collected from a total of ten populations of *Drosophila* (six species) were reported. Although the frequency with which a given polymorphism occurs may vary for the different populations (as the selective factors maintaining it may vary), the examination of data obtained from many populations should minimize the effects of this problem and reveal a consistent pattern, if there are metabolic reasons for certain reactions being sensitive targets of polymorphism-promoting selection. Such a pattern exists, as is clearly demonstrated in Fig. 1, in which the polymorphic allele frequencies of the fourteen enzymes are plotted against their equilibrium constants: the frequencies observed are markedly higher for reactions, with equilibria which lie far to the right.

To obtain an estimate of the average degree of polymorphism associated with each enzyme, the frequency of an enzyme's most common allelic class in each population is multiplied by the sample size of that population, and the products for all populations used to calculate a frequency P

$$P = \Sigma f_i x_i / \Sigma x_i$$

where, for sample i, f is the frequency of the most common allele and x is the sample size. P is thus the average frequency, weighted for sample size, with which the class "most common allele" occurs. One may then consider $(1-P)$ as an index of polymorphism, values of which calculated from the reported surveys suggest that a close correspondence exists between the frequency of enzyme polymorphism and the equilibrium constants of the reactions (Fig. 2).

This same correspondence can be seen in the distribution of examined populations in which high frequency polymorphisms ($\geq 4\%$) are reported (Table 1): high frequency polymorphisms are reported in every case where K_{eq} is large, while no high frequency polymorphisms are reported for freely reversible reactions.

Recent data on the frequency of enzyme polymorphism in extensive studies of human populations are consistent with the above findings[18]: high frequency polymorphisms are reported for glucose-6-phosphate dehydrogenase and phosphoglucomutase, and are not found for 6-phosphogluconate dehydrogenase.

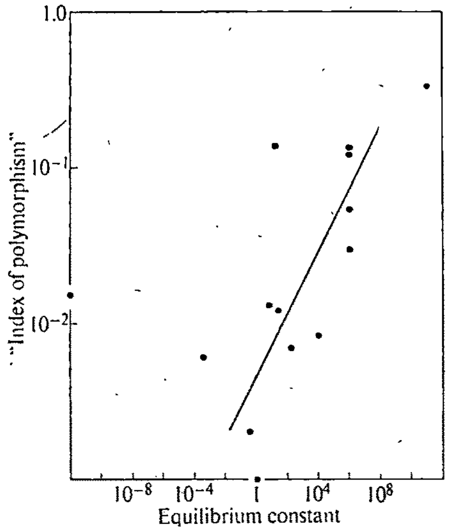

Fig. 2 Relationship of "index of polymorphism" to equilibrium constant. The "index of polymorphism" values are those of Table 1, and reflect the frequency in an average population with which the most common allele of an enzyme does not occur.

Thus, as theoretical considerations predict, a relationship is seen between the occurrence of enzyme polymorphisms and the equilibrium constants of the enzyme reactions involved. The existence of such a relationship argues strongly that enzyme polymorphisms are generally of adaptive significance in nature, and suggests that the magnitude of the observed enzyme polymorph frequencies in natural populations reflects not only the strength of the selection maintaining the polymorphism, but also the "responsiveness" of the metabolic step to that selection.

Evidence for Selective Differences between Cells with an Active Horse *X* Chromosome and Cells with an Active Donkey *X* Chromosome in the Female Mule

THE glucose-6-phosphate dehydrogenase (G6PD) locus is known to be *X*-linked in the horse and donkey[1,2]. The female mule, an interspecific hybrid of these two species, is an obligatory heterozygote for two electrophoretically distinguishable G6PD alleles[1,2].

Studies of the DNA replication patterns of the chromosomes of two female mules by Mukherjee *et al.*[3,4] have shown that, in about half the cells investigated in each animal, the *X* chromosome derived from the female parent (the horse *X*) was late replicating and the *X* chromosome derived from the male parent (the donkey *X*), was early replicating; the reverse pattern obtained in the other half of the cells. Hamerton *et al.*[5] found in three female mules, however, that most lymphocytes and fibroblasts had a late replicating donkey *X* chromosome and early replicating horse *X* chromosome. The distribution was significantly different from the roughly equal representation of cell types noted by Mukherjee *et al.* In the only cell line studied electrophoretically by Hamerton *et al.*, horse G6PD was preferentially expressed, consistent with the hypothesis that the early replicating mammalian *X* chromosome in females is the active one[6]. The observations of the latter workers suggest that in some female mules, either (1) the donkey *X* chromosome is preferentially inactivated early in development, or (and) (2) cells with an active horse *X* chromosome have a selective advantage in at least some tissues during ontogeny.

Table 1 G6PD Phenotypes of Female Mules

Predominant phenotype	Cervical cord	Pancreas	Parotid	Liver	Lung	Thyroid
H>D	20 (18)	19 (12)	23 (15)	9 (6)	8 (8)	8 (6)
H≃D	1 (1)	4 (4)	4 (3)	12 (7)	11 (5)	12 (9)
D>H	2 (2)	4 (3)	3 (3)	13 (8)	6 (4)	9 (5)

The number of animals with the observed phenotypes are listed. Not all organs from every animal could be investigated, but in twenty-two of the fifty-four animals at least five of the six organs listed in the table were studied. The results for these twenty-two animals are listed in parentheses. The patterns were scored independently by E. B. H. and L. D. B. and the sample rerun if there was a discrepancy or uncertainty (see Fig. 1). Examination of blood samples revealed that the horse band was the usual predominant one here also. Mixing experiments with variable proportions of donkey and horse blood samples with known activity indicated that, when the bands of approximately equal intensity were observed, there was at least 35% activity of the major component in the mixture. In a mule in which expression of donkey and horse phenotype was close to equality, there was no observed difference in the proportion of parental phenotype between reticulocyte-rich and reticulocyte-poor preparations, although there was less activity in the latter. Similarly, there was no observed difference between fresh and stored cells in the proportion of parental phenotype, although activity was lower in stored cells. The specific activities of G6PD in peripheral blood of a young donkey and of a young horse were within 10% of each other. Earlier studies[8] suggested that the donkey phenotype was preferentially expressed in liver, but this no longer seems likely.

We have investigated this question by studying the G6PD phenotypes of samples from tissues and organs of fifty-four female mules. The results for representative organs are listed in Table 1. Examples of patterns and their interpretation are illustrated in Fig. 1.

There were two organ types: those in which the horse phenotype was usually predominant, and those in which expression was not significantly different from what would be expected on a random basis. In none of the organs studied was the donkey phenotype the usual predominant one. If *X* inactivation were non-random, and occurred at the early

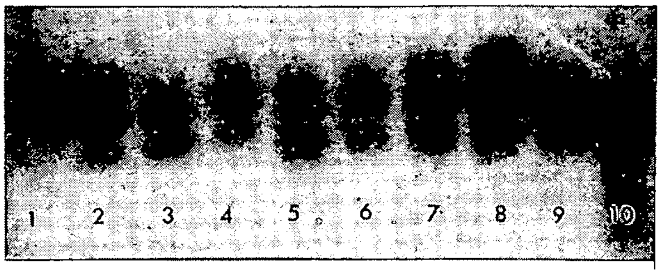

Fig. 1 The bands in the slots at extreme left (1) and right (10) illustrate donkey (D) and horse (H) patterns respectively. The other samples, from pancreas and parotid, were interpreted from left to right as follows: (2) D > H, (3) H > D, (4) ?, (repeat), (5) H > D, (6) H > D, (7) ? H≃D, (repeat), (8) D > H, (9) H > D. All organs were studied using starch gel electrophoresis in EBT buffer with standard methods[9] at *p*H 8.6. Almost all animals were relatively old. Organ samples were collected at the abattoir on dry ice about 60–120 min after death and exsanguination. Blood was obtained in citrate about 5–15 min after death and stored at 4° C.

stage usually hypothesized in the mammalian female embryo, representation of the favoured allele should be relatively uniform in all derived tissues, unless cell selection in particular organs had also occurred. Since X inactivation is thought to occur at about the blastocyst stage[7], before observable organ differentiation, it seems unlikely that preferential inactivation has occurred just in the cell precursors of particular organs. It seems more probable that X-linked alleles of the donkey and horse have had different effects during development and maturation, with a relative selective advantage for cells with an active horse X chromosome in organs such as the parotid gland. But preferential expression of the horse X chromosome in these latter organs did not occur in all animals studied, indicating that the observed phenomenon represents a trend rather than a uniform developmental event in the female mule. Thus discrepancies between studies such as those of Hamerton *et al.* and Mukherjee *et al.* seem likely to reflect sampling differences in animals studied.

An alternative explanation for the observed distribution should be mentioned. Unknown organ specific factors may have differentially suppressed (or enhanced) expression of a particular parental G6PD phenotype (for example, perhaps inhibiting expression of the donkey band in cervical cord, pancreas and so on). Although this seems unlikely, it cannot be completely excluded. But when samples of pancreas with horse phenotype were mixed with samples of other organs which expressed the donkey phenotype, there was no evidence for an inhibiting factor.

New Determination of Australopithecine Height

AN estimation of the body height of two robust australopithecines (Sk 82 and Sk 97) is attempted here on the basis of a ratio between femoral head diameter and body height in modern *Homo sapiens*. Coon, using the fibula and tibia from the "*Zinjanthropus*" living floor at Olduvai, has estimated[1] three different heights for this creature or creatures: 144.5 cm (4 feet 8 inches); 136 cm (4 feet 6 inches); and 152.4 cm (5 feet). Lovejoy and Heiple, using specimens from Sterkfontein (STS 14, STS 34 and TM 1513), have reconstructed[2] a height for the gracile australopithecines at 106.7 cm–109.2 cm (3 feet 6 inches–3 feet 7 inches). An estimation has never been made, however, for the height of an undisputed robust australopithecine.

Because australopithecines were fully erect and bipedal[3] it is possible to apply postcranial information derived from modern *Homo sapiens* to australopithecines; the mechanical relations which hold true for modern bipedal *Homo sapiens* will also apply therefore to bipedal australopithecines. I selected fifty specimens (thirty males and twenty females) at random from the Hamann-Todd Collection of modern *Homo sapiens* in the Cleveland Museum of Natural History. I defined terms and measurements as follows. Femoral head maximum diameter: the diameter of the femoral head taken in the horizontal plane with the femur resting on the condyles and trochanter. Femoral head minimum diameter: the diameter of the femoral head taken at right angles to the plane of maximum diameter. I took care to avoid measuring non-weight bearing surfaces or protrusions. Circumference: the circumference of the femoral head taken at the greatest measurement of weight bearing area on the head. Calculated area: the head of the femur was considered as a half sphere. I used the formula, $\text{area} = 2\pi r^2$ (r, radius), half the value of the surface sphere.

The specimen files of the Hamann-Todd Collection provided body heights. All measurements are in centimetres or, in the case of areas, in centimetres^2, and were taken with a Vernier calliper accurate to a hundredth of a millimetre and a cloth tape accurate to one millimetre. Rechecking occasional specimens for all measurements showed that the values obtained originally were at least 98% accurate.

Determinations were made to indicate which measurement, area or diameter would relate best with body height. By correlation analysis, I found that the average diameter of the head (midpoint between maximum and minimum) correlated better than the surface area (a correlation of 0.648 as opposed to 0.627) and I used it in all further calculations and considerations.

Using a least mean squares two variable regression I then calculated the line of best fit for the data. The equation of this line is

$$\text{body height} = 13.29\times + 108.59$$

The average distance of actual body height from this line is 3.2%, or 5.4 cm. I calculated absolute range of error using the body heights furthest removed from the line of best fit even though these heights may be anomalous. This range of absolute error is +8.2%, −7.4%. I then used this formula to predict the body height of Sk 82 as 151 cm (4 feet 11.5 inches) and Sk 97 as 157 cm (5 feet 1.5 inches). Taking average range of error into account, the range of probable heights for these specimens is

Sk 82	146–156 cm
Sk 97	152–161 cm

I see no reason why this method and formula cannot be used to estimate the height of any bipedal, erect hominid within the average range of error.

I thank Miss Patricia Helwig, Assistant Curator of Collections, and the Cleveland Museum of Natural History for their assistance in making the Hamann-Todd Collection available.

BOOK REVIEWS

Empiricist Physician

Fundamenta Medicinae. By Friedrich Hoffmann. Translated and introduced by Lester S. King. (History of Science Library: Primary Sources.) Pp. xxvi + 142. (Macdonald: London; Elsevier: New York, January 1971.) £3.

THE seventeenth century was fertile with new ideas in medicine and science. Long established Aristotelian doctrines began to crumble before the assault of Baconian empiricism and atomism modified by Descartes, Gassendi and Boyle: the emergence of the iatrochemical and iatromechanical "schools" of medicine completed the rout. It is tempting to classify seventeenth century physicians into various "schools" such as Galenist, iatrochemist or iatrophysicist, but these categories, favoured by latter-day interpreters, were not so clearly defined. In spite of the increased knowledge of scientific medicine, adherents of the chemical or mechanical schools did not really succeed in discarding Galenic remedies or dispensing with the basic tenets of humoral pathology. In this respect Friedrich Hoffmann (1660–1742) was typical of his times.

Born in Halle, Hoffmann studied medicine at Jena and Erfurt, qualifying in 1681. After visiting medical schools in France, Holland and England (where he met Boyle) he returned to practise in Minden and Halberstadt. In 1693 Frederick III invited him to become Professor of Medicine at Halle and, apart from a few years in Berlin as court physician, Hoffmann spent the rest of his life there as a university professor. His interest in medical education led him in 1695 to publish his *Fundamenta Medicinae* as an introduction to systematic medicine.

Hoffmann's faith in scientific medicine is clear from his introduction. "Mechanics alone, wedded to anatomy and chemistry," he wrote, "has so far led natural and medical science from a low position to an exalted one." Although he was able to interpret physiological processes in mechanical terms (his theory of disease too is a mixture of humoral pathology and atomic theory). Hoffmann found it difficult to explain mental processes in similar terms. After removing the theological concept of "soul" beyond the realm of his treatise, Hoffmann tried to reconcile the rational, volitional functions of the mind with the mechanical functions of the body. He postulated that sensory perception and muscular movement were due to the animal spirits controlled by the sensitive soul—a concept expounded by Willis in *De Anima Brutorum* (1672). His diagnostics, hygiene and therapeutics were concerned with the "art" of medicine and, like Sydenham, Hoffmann followed Hippocratic principles based on generalizations drawn from his own experience. He regarded body fluids as the site of disease and stressed the diagnostic importance of analysing blood, saliva, perspiration, lymph, urine and "spirits". An example of his diagnostic empiricism is the statement that "red urine without fever indicates scurvy". The maintenance of health he thought depended on the balanced interaction of the "six non-naturals—air, food and drink, sleep, useful activities and rest, evacuation and repletion and the emotions and passions". Hoffmann's therapeutics were based on his own experience of drug action within the theoretical framework of humoral pathology. He used Galenicals rather than chemical remedies, and although his theory of drug action was essentially mechanical, his actual prescribing was reassuringly empirical. Thus there was a conflict between the art of the physician using drugs based on past experience, and the scientific doctor anxious to propagate new discoveries in physics and chemistry.

This small volume precisely translated and usefully introduced by Dr Lester King is of general interest to the medical historian and essential reading for the seventeenth century specialist.

KENNETH DEWHURST

Small Mammals

Energy Flow Through Small Mammal Populations. Edited by K. Petrusewicz and L. Pyszkowski. (Proceedings of IBP Meeting on Secondary Productivity in Small Mammal Populations, held in Oxford, England, July 29th to August 2nd, 1968.) Pp. 298. (Polish Scientific: Warszawa, 1969/1970.)

THIS volume contains the proceedings of a meeting held under the auspices of the International Biological Programme and yet, from the contents, one might get the impression that work on small mammals is non-existent in Africa, Asia, Australasia and South America. Of the fifty-six participants from fourteen countries, twenty-two came from central or eastern Europe five from North America and the remainder from western Europe. Twenty-two of the thirty-one contributions were written by ecologists from eastern Europe and surely this emphasizes the activity and leadership of these scientists within the context of IBP small mammal ecology.

The contents refer primarily to European work but this does not detract from their importance to small mammal ecology throughout the world. The contributions are grouped into four major sections: (1) standing crop evaluations and dynamics of numbers; (2) food resources and bioenergetic parameters; (3) reproduction and survival and (4) energy flow and productivity estimations. The eleven papers in the first section critically examine methods for estimating population density. It is clear that none of the currently used methods are entirely satisfactory for making absolute density estimates; however, both the mark-release-recapture and the standard minimum removal methods can, when combined with a knowledge of home range and residency, give rise to acceptable estimates. Ingenious methods involving the use of coloured baits and/or radioisotopes are suggested for the determination, among other things, of residency and home range.

The second section comprises nine papers and these, although dealing with the common theme of food resources and bioenergetic parameters, are a miscellaneous collection. In one instance the effect of small mammals on vegetation is considered, in others the effect of different food types on the animals is discussed. Yet other papers are methodological in nature, or deal with seasonal changes in the energy content or respiratory rate of single species.

Two of the papers in the third section tackle the difficult problems of estimating the number of young born into a population and the average length of life of small mammals. Criticism is levelled at the practice of assuming exponential population growth in certain species and different methods of estimating longevity are compared.

The final section on energy flow and productivity estimations contains six papers. It is interesting to note that although a bank vole has an average life expectancy of up to 3.66 months it is clear that some 60 per cent of its production occurs within the first 0.75 months of its life. This underlines the necessity of finding ways to study what is normally regarded as a non-trappable part of the population. The same conclusion is reached in another paper which deals with the field vole. The remaining papers are primarily concerned with food consumption by small rodents and it would appear that these animals rarely eat more than 1 to 2 per cent of the primary production potentially available to them. This suggests that food might not be a limiting factor to the size of some populations, although one author is careful to point out that food might become a critical factor which limits those overwintering populations which follow a peak in vole numbers.

Clearly, this volume summarizes a wealth of information about diverse matters relating to energy flow through small mammal populations. Typographical errors occur frequently in the text but in no instance did I find them particularly misleading and therefore I have refrained from detailing them. In conclusion it must be said that any mammalogist or ecologist professing an interest in small mammal population density estimates, production or energy flow would be doing himself a disservice if he did not consult this publication.

JOHN PHILLIPSON

Scientific Psychiatry

Psychiatry as a Behavioral Science. Edited by David A. Hamburg. (The Behavioral and Social Sciences Survey: Psychiatry Panel.) Pp. xii+114. (Prentice-Hall: Englewood Cliffs, New Jersey, 1970.) $5.95.

SOMEONE once described a camel as a horse that had been designed by a committee. A book written by a committee starts off at a similar disadvantage. This work, one of a series of reports for the public initiated by the US National Academy of Science and the Social Science Research Council, was prepared by a distinguished panel of American scientists. It aims to provide a comprehensive review of psychiatry as a behavioural science, especially in its scientific and research aspects, and, hopefully, to "constitute a basis for an informed, effective national policy to strengthen and develop" these fields. With the public view of psychiatry dominated by the images of the couch and the asylum, the treatment of neurotic private patients by psychoanalysts, and the confinement of psychotic patients in large mental hospitals, there is certainly room for an entertaining and stimulating review of the areas of expansion in modern psychiatry.

Although this volume provides a fairly wide ranging survey of the field of recent and current research in psychiatry, the survey is patchy and by no means as up to date as one expects from a work published in 1970—much of it could have been written five years ago or more. Psychoanalysis is perhaps over-represented for a study of behavioural science; and the emphasis is almost entirely on American work. The presentation is terse and irregular, and manages to be too specific and technical for the lay reader in many passages, as well as too vague and lacking in detail for the professional reader. There is an intelligent and reasonably selective list of annotated references.

The style of writing is turgid and uniformly woolly, which is unpardonable when dealing with such a lively and potentially exciting subject. The layout and design are singularly uninspiring, and the long slabs of grey type are not always easy to read. Perhaps the major weakness of the book is the common one of aiming at a great many targets and missing most of them. It is neither sufficiently clear and attractive to interest and inform many members of the informed public, nor sufficiently critical and specific to be really helpful in guiding future research and developments in psychiatry.

MICHAEL A. SIMPSON

Poor Substitute

Optical Properties of Solids. Edited by E. D. Haidemenakis. (Lectures and Seminars presented at the Fifth Chania International Conference, held at Chania, Crete, Greece, June 30–July 10, 1969.) Pp. xv+520. (Gordon and Breach: New York and London, November 1970.) £12.25; $9.50.

THIS publication covers optical studies in the alkali halides, the inert gases, semiconductors and magnetic insulators but gives only slight coverage to optical studies of metals. Of especial interest is the review by Seraphin of the use of modulated reflectance in the study of band structures; he shows how the technique can be used to separate the massive background of non-critical optical transitions from the smaller contribution due to the critical points, which are nevertheless essential in the adjustment of theoretical band structures.

The contributions by Button and Kaplan on spectroscopy at sub-millimetre and far infrared wavelengths, respectively, bear on semiconductor problems. The use of high frequency photons to excite cyclotron resonance or some other transition between allowed electron states makes possible an order of magnitude increase of resolution compared with that available at microwave frequencies and allows the application of Fourier spectroscopy and the use of resonant photoconductivity as a detection system.

The optical properties of the alkali halides and the inert gases seem to be the simplest possible, and several papers in these conference proceedings concentrate on these materials. Optical properties are evidently better understood than for semiconductors. A paper by Zawadzki develops the analogy between free relativistic electrons and electrons in a narrow gap semiconductor, applying the ideas to the behaviour of electrons in crossed electric and magnetic fields and especially to the optical properties of semiconductors under such conditions. Moriya's review of optical excitation of magnons in spin systems describes a field of growing interest rather sketchily and with no experimental details, only references to the original literature.

Such papers draw attention to the conflict between the more conventional review literature and conference proceedings, in that the inadequacies of some of the reviews in this publication force the reader back to the original literature at an earlier stage than is usual in the study of a review. If the excessive cost of this book is set beside its value to the physicist, it is probably not a book to own but one to be borrowed from a library.

ALEXANDER D. C. GRASSIE

Analysing Proteins

Protein Sequence Determination: Methods and Techniques. By S. Blackburn. Pp. ix+292. (Marcel Dekker: New York, September 1970.) £8; $16.75.

THIS excellent account of protein sequence analysis will be useful to chemists, biochemists, molecular biologists and others who require a practical guide to the subject. Automated analysis is still very much in its infancy and, as the author points out, sequencing a protein is not yet a routine operation, each protein presenting a problem in its own right. In twenty chapters the sequencing strategy is revealed with the enthusiasm to be expected from an experienced worker in the field.

The book covers cleavage of disulphide linkages; specific and non-specific cleavage of proteins by enzymes, electrophilic reagents, acid and alkali; fractionation of mixtures of peptides by precipitation, gel filtration, ion exchange chromatography, paper chromatography and electrophoresis; end group determination, ordering the peptide fragments, radioactive techniques; and finally, mass spectrometric and X-ray crystallographic techniques. The latter techniques have for good reasons been discussed only briefly, but sufficient information is provided to make possible a useful comparison of data obtained by X-ray analysis with those obtained by conventional chemical techniques. At the beginning of each chapter the principles involved are stated concisely in a homely style and these are followed by practical details of experimental procedures. An excellent job has been done in selecting these practical examples, most of them allowing the worker to take his problem directly to the bench without reference to the original literature. A list of sources is, however, available at the end of each section.

The book is not overburdened with tables and figures, and abounds in sound advice and hints on how to avoid pitfalls. It forms a companion volume to the author's earlier *Amino Acid Determination: Methods and Techniques*, but can be read and used independently. The level of proof reading was quite good although a curious chapter heading was missed on page VIII. The publisher could have been a little more generous with the subject index. Overall the book fulfils its aims and should be well received by research workers who have an interest in peptide and protein sequence data. J. LEGGETT BAILEY

Chain Genetics

The Genetic Markers of Human Immunoglobulins. By R. Grubb. (Molecular Biology, Biochemistry and Biophysics, Vol. 8.) Pp. xii+152. (Chapman and Hall: London; Springer–Verlag: Berlin and New York, November 1970.) £4.90.

THE immunoglobulins (Igs) are unique among proteins in their diversity of structure and function. The discovery in 1956 of genetic markers on human and rabbit Igs by the author of this book and by Oudin, respectively, was therefore of particular significance. The subsequent intensive study of these markers has provided an essential framework for understanding the genetic control of antibody synthesis, and has delineated several features of great interest with regard to the assembly of antibody molecules and the differentiation and cooperation of cells which produce antibodies. Genetic markers have also been useful in studies of the phylogeny, ethnic features and ontogeny of immunoglobulins, and forensic pathologists have used them with practical effect in cases of disputed paternity and confusion of newborn infants in maternity hospitals. They can be of unique value in the latter case because the infant's genotype for Ig synthesis is not expressed at birth and its circulating IgG is for practical purposes exclusively of maternal origin.

Genetic markers are now known for three of the seven major classes of immunoglobulin heavy and light chains. Identification of their many polymorphic forms involves the use of human antisera which specifically agglutinate red blood cells coated with human immunoglobulin. The anti-human γ-globulins used in these tests originate principally in patients who have had multiple blood transfusions or in subjects who may be apparently healthy or afflicted with rheumatoid arthritis. The clinical significance of these antibodies in the latter context and their possible role in the pathogenesis of disease are matters of continuing controversy and interest.

All these intriguing ramifications of an important topic are lucidly outlined in the first eighty-five pages of this admirable, small book. The text is supported by a wealth of tabulated data and a concluding appendix of thirty pages provides a comprehensive source for the original references, mode of detection, ethnic distribution, molecular localization and inheritance of some thirty genetic factors which have been detected on human immunoglobulins. This book will be of great value as a succinct and authoritative source for immunologists, geneticists, clinicians and others interested in the many sided problems of antibody synthesis. It is regrettable that the author's economy and accuracy were not emulated by the publishers who are responsible for the inflated price and several printing errors—some diverting, such as that on page 82, which concerns "the mouse lamb dalight chains" of IgM. S. COHEN

Vibrations

Low-Frequency Vibrations of Inorganic and Coordination Compounds. By John R. Ferraro. Pp. xiv+309. (Plenum: New York, 1971.)

IMPORTANT developments in far infrared instrumentation during the past ten years have led to a considerable increase in the published data on low frequency vibrations of molecules and ions, which are not only of interest to spectroscopists but of potential value to other chemists. In this book the author, who has published a considerable number of research papers in this field, sets out to demonstrate the usefulness to inorganic chemists of infrared absorption measurements below 650 cm^{-1} on inorganic compounds.

A brief introduction sketches the history of far infrared measurements and the experimental and interpretative problems of this region of the spectrum, and is followed by a chapter describing commercial instruments including interferometers, some in considerable detail but others only in briefest outline. A comparison of the relative merits of spectrometers and interferometers, probably of greater general interest than the rest of the chapter, is unfortunately presented in brief tabular form, with references to other texts. The third chapter summarizes useful data on window materials and some common organic solvents. Calibration is also briefly discussed but one is referred to other texts for many of the calibration data. The fourth chapter sketches the use of inelastic neutron scattering and high pressure techniques in vibrational studies, again with references to other sources for details.

The next four chapters, comprising more than two-thirds of the book, present data (including those from Raman measurements) and discussion on metal–oxygen, metal–halogen, metal–nitrogen and miscellaneous metal–ligand vibrations. Many of the data are in tabular form and the presentation is similar to that in other books of this type. The final chapter very briefly summarizes some results on ion-pair and lattice vibrations, clathrate vibrations and low frequency electronic transitions. Two appendices give tables of crystal site symmetries and subgroup correlations, and describe a method for factor group analysis of crystal vibrations.

This book undertakes to cover a very wide field embracing almost the whole of metal–ligand vibrations, which is scarcely reduced by the rather artificial limitation to frequencies below 650 cm^{-1}. In order to save space much use is made of references to other texts for detailed discussion, and on many topics no detailed or critical account is given. References are included up to 1969, but, the author says, the book does not claim complete coverage of topics or references, and there are some obvious gaps. The book therefore seems to be chiefly of value to newcomers and non-specialists in this field, giving in one volume brief accounts of both experimental and interpretative matters. While also of use to specialists as a recent source of references, its value as a convenient source of data is somewhat reduced by its lack of comprehensiveness on details.

J. A. CREIGHTON

Spectra Galore

Spectroscopy in Inorganic Chemistry. Vol. 1. Edited by John R. Ferraro and C. N. R. Rao. Pp. xiii+410. (Academic: New York and London, October 1970.) $19.50; £9.10.

THE two volume treatise of which this volume is the first part is more specialized than its title suggests. It describes recent advances in inorganic spectroscopy but omits well known aspects of spectroscopy such as electronic or vibrational spectroscopy and their applications to coordination chemistry as well as lengthy discussions of instruments and methods. The articles are intended not as complete compilations but as reports of the present position and of future potentialities.

There has not been much time for some of the new results to be digested, and many of the chapters are oriented towards methods and methodology (even when these can be found elsewhere) rather than towards the interpretation of spectra in terms of structure and bonding. Many chapters are anecdotal rather than correlative, some are too elementary. Thus section D of the chapter on high-resolution NMR begins: "The electronic environment in molecules does one more subtle thing. It couples magnetic nuclei present in the same molecule. Such a coupling is experimentally observed as a splitting of NMR lines." (Surprise, surprise.) This chapter describes some useful inorganic studies, but fails to mention superconducting magnets, liquid crystals and Fourier transforms.

Some of the chapters are competently written, a few well written. The foreign language literature, however, and its English translations, is often poorly served. The first article refers to one German and to two (translated) Japanese papers in 65 references. The review of Mössbauer spectroscopy, which is a German invention, refers to two German papers (by Mössbauer), two Japanese and one (translated) Russian paper among 90 references. Editors (on both sides of language barriers) should encourage their authors in scientific internationalism, for this lack of effort, which is not necessarily chauvinism, is only too common. In a volume costing £9 (£1 per article of about 45 pp.) we expect coverage of the less accessible, and no less relevant, parts of the chosen fields.

There are other examples of parochialism. Thus the description of the early work in matrix isolation spectroscopy refers to Pimentel but not to Norman and Porter, Rice or Lewis and Lipkin[1].

While counting references, we could congratulate the authors of the chapter on soft X-ray spectroscopy on their activity in this field, for 23.5% of their references are to their own work. They tell us that their examples were chosen to show "typical results", but the references, if not the text, should aim at a reasonable coverage and should mention other useful accounts that are available[2]. Their suggestion (p. 210) that the future significance of this method lies in the interpretation of spectra rather than in the determination of concentration is misleading; they themselves report (p. 242) that the analysis of rocks by X-ray emission spectroscopy was shown (1965) to be better than with wet chemical techniques.

As the book goes on, the proof reading flags, and a strange chemistry, of nigrogen, cynides and ferrocynides, develops. We need these reviews; but the high cost of distribution justifies a plea for a high standard of preparation.

Hot Polymers

Thermal Stability of Polymers. Vol. 1. By Robert T. Conley. (Monographs in Macromolecular Chemistry.) Pp. x+644. (Marcel Dekker: New York, October 1970.) $44.50.

THE wide uses to which polymeric materials, especially those of synthetic origin, are now applied make it imperative that information on properties and performance should be as complete as possible. Plastics, rubbers and fibres are often subjected to environmental conditions which may have a profound effect on their chemical, physical and mechanical properties. Behaviour at elevated temperatures is an important factor when selecting suitable materials, and this book provides a welcome collective survey on thermal and thermal/oxidative degradation. Edited by Professor Conley of Wright State University, Dayton, Ohio, it has fourteen chapters, by experts in US academic, industrial and research organizations and one contributor from the UK (Dr Wright of the Royal Aircraft Establishment, Farnborough).

In two initial chapters, Professor Conley discusses the general concepts of polymer properties, degradation processes, molecular structure, and stability criteria, drawing attention to structures which contribute to thermal resistance. Chapters by R. H. Boyd and A. V. Tobolsky and co-authors then review the more theoretical aspects of thermal depolymerization, scission processes and polymer oxidation, providing a background essential for appreciation of later chapters where important classes of polymers are considered. These deal with polyolefines (R. H. Hansen), rubbers (E. M. Bevilacqua) and fluorocarbon polymers (W. W. Wright). Professor Conley and co-authors provide chapters on vinyl and acrylic polymers; on polyamide, polyimide and related condensates, polyesters and polyethers; on thermosetting polymers (phenolic, nitrogen, furan and epoxy resins); and on cellulosic products. The remaining chapters are by G. P. Shulman who deals with heterocyclic polymers and to some extent covers the same field as Conley's chapter ten, and by J. Economy and J. H. Mason on the behaviour of some inorganic polymers.

Each chapter is accompanied by lists of references to the more important papers (usually up to 1967), so giving an extensive but sometimes noncritical review since the treatment varies with the individual contributors. While the editor has endeavoured to bring the contributions together in a uniform manner, some repetition or overlap is evident (particularly in the tenth and thirteenth chapters). To some extent this may be an advantage in that the chapters become self-contained. There are places where the reader will see omissions or be critical of the authors' interpretation of published information, evident in discussions on acrylic, vinyl and olefine polymers. Another feature is the apparent insufficient attention given to technological implications, particularly on the use of stabilizers, antioxidants and modified process conditions, all of major importance in polymer-using industries. Again, one notes that while there is much on the degradation of polyacrylonitrile, the bearing of this on carbon fibre formation is not stressed; nor are polyurethanes dealt with.

Author and subject indexes are provided, although the latter could have been more comprehensive, and I noticed some typographical errors throughout the text.

The book presents a useful addition to the literature and those who are concerned with the behaviour of polymers in conditions where thermal and oxidative influences are encountered will find it to be of particular value. Unfortunately, the high price may well limit its general availability and it is likely to be consulted in libraries rather than purchased for personal use. I look forward to the second volume, now in preparation, and although the possible content has not been indicated it is hoped that this will be complementary to the first volume and perhaps be concerned with other polymer types and with thermal degradation as it affects processing and properties rather than chemical structure.

R. J. W. REYNOLDS

CORRESPONDENCE

Smoking and Cancer

SIR,—In his letter (*Nature*, **231**, 543; 1971) on smoking and lung cancer, Dr Sterling states that he had set up a panel to provide authoritative guidance on the link between smoking and disease, and invited Dr Cuyler Hammond to meet this panel. He also requested Dr Hammond to provide the panel with the unpublished data from his own studies: Dr Hammond refused.

He then develops a highly personal attack on Dr Hammond in which he implies that this refusal casts serious doubt on Dr Hammond's reports on the association between smoking and lung cancer.

More seriously, however, Dr Sterling's letter also implies that this refusal by Dr Hammond casts similar doubt on other studies on the relationship between lung cancer and smoking. Thus, Dr Sterling impugnes the integrity and competence of the numerous scientists and committees in many countries who have reviewed exhaustively the extensive data published on this subject[1,2]. If Dr Sterling disagrees with their conclusions he should do so in a carefully documented critique of all the published data rather than by singling out Dr Hammond's study for personal criticism.

I suspect the reason for Dr Hammond's unwillingness to meet with Dr Sterling's panel is that he does not feel that his time would be best spent discussing and presenting data to yet another group of individuals apparently unfamiliar with the material in the widely explored area of cigarettes and lung cancer. There must be few experts in this field who have studied the literature and not yet reached a decision.

Thus, I believe that Dr Hammond's colleagues will consider that Dr Sterling's tasteless attack constitutes a form of blackmail, and that he was fully justified in his decision not to discuss his data with Dr Sterling's panel. Further, many will draw the conclusion that this attack implies that any scientist who fails to make his data available to any Tom, Dick or Harry is lacking in credibility. This attempt to discredit scientific data and conclusions by character assassination through inference should not be part of the modern scientific approach, and I am surprised that this letter was published in *Nature*.

I have disagreed from time to time with the American Cancer Society on its comments on individual scientific papers, but I have not doubted its good faith and the basic correctness of its wish to bring to public notice the danger of a popular habit, which at best is a thankless task.

Lastly, Dr Sterling should confirm that neither he, nor his department nor his research, are supported by the grant reported to have been made recently to his university by certain industrial interests.

Yours faithfully,
JOHN HIGGINSON

Defoliation by Gypsy Moth

SIR,—In the article "St George versus a Gypsy Moth" (*Nature*, **231**, 142; 1971), *Nature* shows signs of adopting the style of its American contemporary, a consummation devoutly to be abhorred. Your Washington correspondent says that the battle of words over the gypsy moth "has been a walk-over for those who argue that gypsy moths may in all likelihood be less pernicious than the measures taken to exterminate them". Who decided this ? On June 24, 1970, the *New York Times*, which is scarcely a friend of pesticides, reported from Riverhead, Long Island (p. 59): " . . . The caterpillars arrived in large cans and plastic bags brought to the legislative session by more than 50 irate residents of the communities of Shirley, Mastic and Ridge. The residents demanded immediate emergency action to curb this year's invasion which is, according to some agricultural experts, the largest since the moth was introduced into this country in 1869. 'We are in a state of emergency', Mrs Helen Gaylord, of 32 Maple Avenue, in Shirley, told the legislature, 'Our children cannot go out. Our pools are finished for the summer. It's a question of survival—the caterpillars or us'."

Nature states that the USDA, "like many bureaucracies, is kept in motion by force not of reason but of habit", a generalization that also could be unkindly applied to Washington correspondents. Your correspondent also asks the rhetorical question: "Why does the Department of Agriculture persist in pursuing a programme of which the objectives are ill defined, the benefits clearly temporary, the biological consequences unknown because of inadequate research, and the intellectual foundations so shoddy as to destroy any pretensions to academic respectability the department might still hold ?"

The objective of the programme is clearly defined—kill gypsy moth caterpillars. All benefits can be described as temporary, and all biological consequences as unknown. The final phrase is merely name-calling. Stripped of its emotional rhetoric, the article in *Nature* is a one-sided plea for not interfering with "the natural evolution which must take place while gypsy moths find their natural niche" (column 3). This is the standard neo-Luddite plea against pest control. It is voiced most commonly by dwellers in air-conditioned urban buildings. Meanwhile, after a century to "find their natural niche", the gypsy moths are on the move, and are defoliating vast new areas of forest and woodland[1].

Yours faithfully,
THOMAS H. JUKES

NATURE Volume 232 AUGUST 6 1971

Black Arrow Aborts

THE only complaint to make about the abandonment of the development of the Black Arrow rocket (see page 362) is that the decision was not taken several years ago. Since 1964, when the programme was begun, only a few enthusiasts have professed conviction that they knew what Black Arrow might accomplish. To most people, it has been clear all along that the fully developed rocket would be too small to accomplish the tasks which the then government specified for it. The result is that more than £11 million has been for practical purposes wasted on the development programme and on the launching of three rockets at a cost of £2 million each. The question whether the programme should continue has no doubt been brought to a head by the failure last year of an attempt to attain an Earth orbit. In the circumstances, there will clearly be a great many pairs of crossed fingers as the time approaches, later this year, for the attempt to launch the X3 satellite. Whatever happens, however, that will be the last monument to Black Arrow. Thereafter, the British Government will turn, as it might have done in the first place, to the National Aeronautics and Space Administration in the United States. It is earnestly to be hoped that the talk now to be heard of rekindled British interest in a European launcher rocket is, for the time being at least, all smoke and no fire. In the meantime, three questions should be answered—what can be done to prevent similar mistakes in the years ahead, what strategy should be adopted for the development of space research in Britain and what opportunities are there, in this hard-headed world, for making money out of space?

Black Arrow was born of compromise. Quite sensibly, after the unhappy experiences of the early sixties, with the concept of a military rocket able to carry nuclear warheads from one place to another, the British Government was persuaded that it could not set up in business as an independent satellite launcher. That, in any case, was what the European Launcher Development Organization (ELDO) was meant to accomplish but there was a seductive line of argument that there would be serious dangers in contracting out of what was called space technology —the design and operation of solar cells, ion rockets and the like. The result was the decision to develop a launch vehicle capable of putting experimental packages into orbit but not big enough to launch satellites of any practical value in applications. (The scheme for using electrical propulsion driven by solar cells as a means of progressively driving out the orbit of such a satellite to geostationary distances is ingenious enough but unlikely to compete successfully with techniques of satellite launching that achieve a geostationary orbit at one fell swoop.) Worse still, however, the Black Arrow development programme was run on a shoestring. For the first year and a half, until the beginning of 1966, contracts were awarded for periods of three months at a time, with the result that those working on the programme were frustrated and, predictably, by the time Black Arrow was in service, most of what it might have achieved had already been done elsewhere. It is also now a familiar experience, in several other countries as well as the United Kingdom, that it is not safe to base a rocket development project on a single launching once a year. The waste of time and money if one rocket should fail (as one and a half have done with Black Arrow) cancels out the economies that parsimony brings. This is the point which the Estimates Committee of the House of Commons singled out for special complaint in 1967, but nothing much has been done since then to put the programme on a better footing. The moral, of course is that there is no point in trying to enter a quickly growing branch of advanced technology with only just enough resources to wet the feet. Black Arrow has been an unnecessary but expensive product of wishful thinking.

What should happen next? Plainly the British Government cannot hope to mount programmes comparable in scale even with the malnourished Black Arrow programme without spending much larger sums of money than it is accustomed to devote to work like this. In the past five years, the Black Arrow programme hasaccounted for more than one-sixth of expenditure on space research and technology carried out by British organizations. At the moment, Black Arrow is running at about twenty per cent of this same expenditure. Evidently it would be quite out of the question to mount a more effective programme to succeed Black Arrow without increasing the space budget by several million pounds a year and by recognizing that close on a half of all national expenditure on space research and technology would go on this new venture. That, evidently, is out of the question. In any case, the defence research programme, which has already led to the valuable Skynet communications satellite, is probably a sufficient guarantee that British laboratories will know what the Joneses are doing even if they cannot keep up with them in every respect. In the circumstances, British policy should aim at making sure that at least some British organizations will be able to make effective bids for the Intelsat contract that should then become available for building communications satellites. Nobody should be ashamed of asking NASA to keep on launching scientific satellites labelled with a Union Jack. What matters there, as every scientist will say, is whether the satellites are launched successfully and whether they function well when once in orbit.

But is there money to be made? It is perhaps salutary to recall that communications satellites are potentially valuable because they are, above all, cheap. The first five copies of the Intelsat IV satellite, each with up to 6,000 telephone circuits or their equivalent, cost Intelsat $72 million and it seems to be acknowledged that the price would have been lower if Comsat had been a better manager. The second five copies cost less than half as much, and are likely to satisfy the needs of Intelsat for the rest of this decade. The questions that governments like the British should ask themselves is how much it may be worth spending to win a chance of competing successfully for a business that seems to amount to something of the order of $100 million a decade, or $10 to $20 million a year. On the face of things, it would be safer to put the money into a programme for developing a technology in some more reliable market, typewriters for example. To be sure, the enthusiasts such as the British Aircraft Corporation say that in due course there will be a rich market for supplying communications satellites to individual countries or groups of countries wishing to have one to themselves, or even in broadcasting educational television. The trouble here is that the market may not exist at all—much depends on the outcome of experiments still to be mounted as well as on the regulations adopted by governments to control the importation of television programmes from outside. And applications of communications satellites other than in telecommunications, socially valuable though they may be, are necessarily less prolific markets for the satellite builders. From a strictly national point of view, in other words, as well as from all others, it is essential that the British Government, now embarked on yet another review of "the national space technology programme", should try to head off the enthusiasm of the country's aerospace industry as it calls itself, and that it should persuade them to put their backs into more mundane activities such as telephone switching equipment.

Sheep and Goats

GOVERNMENTS on both sides of the Atlantic have in the past week been perplexed by the need to make decisions about the future of important enterprises. In the United States, the Senate on Monday this week did finally agree, over Mr William Proxmire's protesting but much alive body, to provide a guarantee for a bank loan to the Lockheed Company so as to provide it with the finance necessary to keep the company alive. In Britain, the government has taken a similar view about its attitude towards the computer company International Computers Limited, which in the past few months has from time to time been alarmed by harsh words from government ministers anxious to impress on all kinds of industries that nothing stands between a company and bankruptcy except profit. Although no money will change hands in an obvious sense, ICL will be helped along by government research contracts and will also benefit from a procurement policy likely in the future to be more effective than in the past (see page 360). Other computer companies in Britain are understandably upset by this development, especially because many of them must have been calculating that the impending entry of Britain into the EEC would have been a splendid way of extending their influence on the mainland.

In case the British Government should be considered to be backsliding from the spartan views which Mr John Davies at the Department of Trade and Industry has been advocating in the past year, however, no less a person than Mr Davies himself stood up in the House of Commons last Friday to pronounce the end of government support for Upper Clyde Shipbuilders Limited, an amalgamation of four Scottish shipbuilding yards which has been supported since 1967 with a total of £27 million and which is now in bankruptcy. No doubt this decision would have been an even more dramatic incident if the workers affected had meekly joined the dole queue; instead they have quixotically kept on working. But for them and taxpayers everywhere, it may be important to know by what criteria conservative governments in the United States and Britain have decided to go against their principles and prop up lame ducks. Why is Upper Clyde Shipbuilders less deserving than International Computers Limited?

The most obvious difference is that shipbuilding is, so far as Britain is concerned, an ageing industry, while International Computers Limited is at least an enterprise that may bring profit in the years ahead. In other words, it may well seem that what the British Government is doing is prudently to invest in the future and sensibly to wash its hands of the past. The difficulty, of course, is that industrial issues are never as simple as this. Ever since the publication of the Geddes report on shipbuilding five years ago, it has been clear that there is nothing wrong with British shipbuilding except the way in which the industry is organized. There have been too many yards, too many builders of marine engines, too little equipment which is modern and efficient and too casual a sense of the difference between profitability and failure.

Upper Clyde Shipbuilders came into being partly because of the then government's wish to make progress along the lines suggested by the Geddes Commission and partly because of its wish to encourage some novel, almost syndicalist, experiments in labour relations at the Fairfield's yard, one of those now amalgamated into Upper Clyde Shipbuilders. Perhaps, in retrospect, nobody should be surprised that the prospect of closure has stimulated schemes for enabling workers to assume and retain control. Yet the case of British shipbuilding is entirely similar to that of British textiles two decades earlier—too many companies, too little productivity insufficiently compensated for by low wages, too little new machinery and no semblance of financial understanding, let alone control. The Geddes Commission in 1967 would have done well to have spelt this out more clearly. The last government would have done the shipyards as well as its reputation a service by looking for radical solutions to shipbuilders' problems, not by attempting to paper over the cracks with what is now acknowledged to be a theoretical merger.

As things have turned out, the steps that might have been painless four years ago have now been forced on the shipyards, on the government and on the people of Clydeside. In his first statement, last week, Mr John Davies spoke as if the issue was simply a question of cash, and there is of course no doubt that in strictly commercial terms, Upper Clyde Shipbuilders are bankrupt. Even if they were able to finish off their ships on time, they would be almost certain to lose money on them. No doubt the independent (but some say biased) committee which provided the government with advice is right to have said that work would have to be concentrated on two yards, not four, and it is logical for the government to take the line that even such a solution will be acceptable only if private industry seems inclined to take a risk in building ships on the Upper Clyde. Yet is it proper for a government to wash its hands as easily as Mr Davies has done of responsibilities implicitly incurred by its predecessor? Rightly or wrongly, most probably wrongly, Mr Anthony Wedgwood Benn, when Minister of Technology, allowed public funds to be engaged in keeping the Upper Clyde Shipbuilders going from one crisis to the next. By doing so, he helped to create an illusion of security among the 9,000 people on the payroll. Is it permissible now for his successor to pretend that such an implicit commitment can be dismissed simply because the government has changed? It is creditable that Mr Davies's contribution to the debate in the House of Commons last Monday did more to acknowledge that it is unseemly to throw 4,000 people out of work in an area in which unemployment is already high. It is a question whether, in circumstances like these, the government does not owe the community a much more active campaign to help ensure that the consequences of shutdown are ameliorated. This, after all, is one of the continuing roles of governments in advanced societies in which old industries must continually be overtaken by new.

A second complaint against what may be a perfectly respectable decision to recognize the bankruptcy of Upper Clyde Shipbuilders Limited is that the government has in its present way of thinking no means of encouraging the kind of rationalization of the shipbuilding industry which needs to be attempted. It is all very well to say that governments should let industries and companies demonstrate by performance whether they can sink or swim but this is too passive a point of view. There are, after all, carrots as well as sticks, and it should not be beyond the wit of governments such as even the present to devise ways of moulding the shipbuilding industry in Britain into a pattern which is commonly held to be viable. To be sure, there are some theoretical difficulties in the way for those who believe that only the natural tug of war to which industrial companies are naturally exposed can be relied upon to chart the course for the years ahead, but this is like saying (as some heuristically inclined educationists insist) that if you put a child in an empty room and leave him for long enough, he will rediscover Newton's laws. The truth is that there are plenty of ways of combining carrots with sticks so as to catalyse the process of self-discovery. What the shipbuilding industry in Britain needs is more encouragement to invest in new equipment and more vigorous criticism of its performance. The government would do a public service if it recognized that it must play a part in bringing out these conflicting pressures in the industry. After all, there are several candidates in line for similar treatment. After shipbuilding will come the motor car industry. Can machine tools be far behind?

By these standards, the plan to give ICL a sense of security which it has not entirely earned by its own efforts leaves much to be desired. The chief difficulty is that there is no means of knowing whether it is possible to organize a computer company on a strictly national basis. With shipbuilding, it is true, comparatively small enterprises can succeed—the Scandinavians and the Japanese have shown precisely that. But with computer manufacturers, the high cost of meaningful research and development puts computer manufacturing in a class with aircraft manufacture and petroleum production. The chances are that the most straightforward way of launching such an enterprise is to have access to several markets and to several sources of technical skill. It may be the case that the British Government is building up ICL as a kind of dowry with which to join the EEC. It is also of course true that ICL itself has been enterprising in forging links with companies abroad, notably the Control Data Corporation (but its association with RCA has come to an end in the past few weeks). In all the circumstances, there is a danger that the British Government may be seeking to prop up an organization in the wrong pattern. This is the error which its predecessors made, but it may be a little more demeaning that the mistake on this occasion resembles that by means of which tiny governments give themselves an air of going places by sponsoring with taxpayers' money airlines which cannot be commercially viable.

The case of Lockheed is very similar. Ironically, the Senate's narrow endorsement by one vote of the earlier decision by the House of Representatives to guarantee a loan of $250 million to a corporation already in the red to the tune of $400 million came just a week after the first flight of the Douglas DC-10, an aircraft that would be entirely competitive with the Lockheed Tri-Star airbus if the two manufacturers had not insisted in advance that potential customers should place firm orders and make appropriate non-returnable deposits as marks of their good faith. As it happens, the putative customers now regret having placed their orders, for air traffic has lagged behind the forecasts of a few years ago. The ideal outcome of the trouble about Lockheed would have been a merger with Douglas, even though that might well have left the luckless Rolls-Royce with nothing to keep the RB211 engine alive.

What Congress has now done is to help support an entirely laudable organization which is nevertheless cast in the wrong mould—in spite of the buoyancy and the commercial resilience of the American based airlines, the United States is already too small to support three large suppliers of civil aircraft. As with computers, so with aircraft, the development costs are necessarily so high that only multinational companies can hope to be successful. But Lockheed is, like its competitors, also closely tied to national programmes for defence research and development. Congress would have done better for Lockheed, for airlines and for American taxpayers if it had found some way of pushing the company towards a different strategy for organization with less dependence on the domestic market and the local government. Like the British shipbuilders and the British computer manufacturers, American aircraft manufacturers are in danger of strangling themselves with too little imagination. There are no sheep, they are all goats.

100 Years Ago

THE charge against Mr. Hampden of libelling Mr. Wallace was tried on Thursday week in the Secondary's Court. Our readers will remember that a wager of 500*l*. having been made between Mr. Hampden, who affirmed that the world was flat and not round, and Mr. Wallace, it was decided against the former, who thereupon abused Mr. Wallace as a liar and a swindler. The action now tried was for damages for these and other similar libels, and Mr. Hampden was condemned to pay 600*l*. damages.

From Nature, **4**, 287, *August* 10, 1871.

OLD WORLD

GAS CENTRIFUGE

All Set for Bensberg

EUROPEAN uranium enrichers in Britain, Germany and Holland are now able to point to at least one tangible sign of progress—the formal establishment of the German-based company called CENTEC at Bensberg, near Cologne, on July 29. The new company, formally known as CENTEC Gesellschaft für Centrifugentechnik mbH, will be responsible for the research and development programme which, the sponsors hope, will yield a couple of functioning pilot plants by about 1975, one in Britain and one in Holland. When the technical and economic feasibility of gas centrifuge machines for enriching uranium has been assessed, CENTEC will be empowered to design and build enrichment plants to the orders of its customers. As at present foreseen, the principal customer will be a company called URENCO, similarly sponsored by the three governments of Britain, Germany and Holland, which will be able to process and to sell enriched uranium to potential users. Theoretically, CENTEC will also be able to sell enrichment plants to countries not involved in the development programme, but obviously the sponsoring governments will be more anxious to set up as successful suppliers of enriched uranium, with the continuing profit that that will bring, than to supply outside parties with opportunities to set up in competition. URENCO has not yet been formally established, but its shareholders will be, as with CENTEC, the Dutch company Ultra-Centrifuge Nederland NV, the German company Gesellschaft für Nukleare Verfahrenstechnik mbH and British Nuclear Fuels Limited.

Those involved with the new development seem to be as optimistic now as were the three sponsoring governments when news of the possible use of gas centrifuges in uranium enrichment was first made public two years ago. By all accounts, individual centrifuge machines have been tried out separately and in cascade, with the result that the designers are confident that the machines will function. The questions to be decided chiefly concern the cost of production. Mr T. Tuohy, managing director of British Nuclear Fuels Limited and a director of CENTEC, said earlier this week that the obvious target at which to aim is the United States Atomic Energy Commission price of $32 per ton of separated work, the equivalent of $35 per ton delivered in Europe. He said that he and his colleagues were optimistic about the prospects—that this goal could be attained.

The chairman of the board of the new German-based company is Dr Ir Han Hoog, recently retired as a director of Shell Petroleum Limited and its Dutch equivalent. The general manager of the new company is Mr David Peirson, secretary of the UK Atomic Energy Authority for the past sixteen years. The new company's budget is not publicly available, although it is expected that total development costs will be several million pounds. Under the arrangements which have been worked out so far, research contracts will be farmed out by CENTEC to the three shareholding companies. The result is that only the technical staff of CENTEC will be in a position to make an overall assessment of the programme of research and development.

SCIENTISTS' PAY

Calm Before the Storm

BOTH sides involved in the scientists' pay dispute are, this week, taking stock of the situation before the official arbitration tribunal sits next Thursday, August 12. The Institution of Professional Civil Servants (IPCS) has organized a public meeting scheduled for 7.00 p.m. on August 10 at the Central Hall, Westminster, to bring to a climax its campaign that started at Abingdon three weeks ago.

These meetings have attracted large numbers of people but they have produced no visible change in the attitude of the Civil Service Department. A spokesman for the department said earlier this week that he could not comment on the strength of feeling shown at the IPCS meetings, but that the official side's case—based on the findings of the Pay Research Unit—had already been submitted to the tribunal. The unit's report has been interpreted by the government to show that a scientist within the Scientific Civil Service is as well off financially as his counterpart in industry.

The institution counters this by saying that the comparison is unfair in the sense that several of the companies included in the pay research exercise base their salaries on what the government pays scientists. It also says that the government's offer makes no allowance for the fact that the administrative grades within the Civil Service received a pay award earlier this year and so this present offer destroys the concept of internal relativity within the Civil Service.

Mr William McCall, the general secretary of the IPCS, said earlier this week that any independent body would be certain to recognize the merits of the institution's case and that he was confident that the outcome of the tribunal would be favourable to the scientists. Mr McCall also said that if the tribunal does not produce what he expects, he will press for a review of the basis for determining scientists' salaries within the Civil Service.

Whatever the findings of the tribunal, there will be pressure to change the procedure used to determine government scientists' salaries. If there is no award, the IPCS will evidently seek to change the system. If, on the other hand, the tribunal recommends all or even part of the claim, then the whole of the pay research investigation will be invalidated. For outsiders, however, it remains a paradox that the report of this Pay Research Unit is still confidential between the Civil Service Department and the IPCS.

The question of whether the report of the Pay Research Unit should be made public was raised in the House of Commons on July 29 when the Prime Minister, Mr Edward Heath, told Mr Tam Dalyell that the decision to abide by the recommendations of the Pay Research Unit was originally made by the previous government, but that "it does not seem justifiable, when the pay is above those already working outside, that those concerned should still have increases of salary". The Prime Minister added that he would enquire into the possibility of making public the report of the Pay Research Unit.

COMPUTERS

No Breadline for ICL

THE announcement last week by Mr Frederick Corfield, Minister for Aerospace, that the British Government would continue to support International Computers Limited is certainly a shot in the arm for the company, but the decision has aroused some strong feelings among the other computer companies in Britain. These, mostly offshoots of United States corporations, naturally feel hard done by and their strongest complaint is that the minister has apparently reversed previous government policy in granting further research and development money to ICL.

ICL has always been in a privileged position in the supply of computers to government departments, and the new statement will ensure that it remains so. The company's position is determined by single tender orders which involve no competition from other manufacturers. Such preferential treatment should ensure a thriving company, but the signs are that all is not well at ICL, with 1,800 redundancies announced last week to add to the 1,600 announced earlier this year. Sir John Wall, the chairman of ICL, has said, however, that the company is in good shape and that the pessimism about the future is not well founded. Sir John also stated that the cut back in staff was evidence of ICL's determination to live within its resources.

International Business Machines Limited has been maintaining a dignified silence about the events of the past few days, but the Honeywell company has spoken out against the government's action. Mr Donald Brosnan, chairman and managing director of Honeywell, said this week that "the policy works against the British computer industry as a whole and in particular against the development of computing in the public sector. Not only does it stifle competition but it also limits access to international technology".

The question that remains unanswered is whether the confidence placed in ICL is well founded. Are the performance and cost of ICL computers comparable to or better than their competitors? Such a comparison is not possible without a detailed analysis of the needs of a particular user; in particular it depends on the scientific/commercial balance that the computer user needs to achieve.

The computer companies stress that they will only quote performance figures for a particular job assignment. Despite this, however, it is apparent that the Honeywell 6000 series, the IBM 370 series and the ICL 1900 series are comparable and competitive.

With ICL receiving such support from the government and also in view of the pressure that is being exerted on industry and public sector bodies in Britain to buy ICL computers, it is not difficult to understand why the other companies are annoyed. Mr Brosnan expressed the feelings of these companies when he stated that Mr Corfield's statement "ignores the interest of foreign owned companies which manufacture and employ significant numbers of people in the United Kingdom (Honeywell employs 8,000). In so doing it conflicts with other stated government policies of attracting overseas investment to the nation's development areas".

EARTHQUAKE RESEARCH

What Future for Tokyo?

from a Correspondent

THERE is great anxiety among seismologists about the future of the International Institute of Seismology and Earthquake Engineering, set up in Tokyo in 1962 and supported jointly by the Japanese Government and the United Nations Development Programme. The immediate problem is to know how the institute can continue after August 1972, when the present agreement runs out. At what seems to have been a sombre meeting of the senior consultants of the institute in Tokyo in March this year, it was accepted that continuing support for the institute would have to come from the government of Japan and from UNESCO.

The institute has a permanent staff of about twenty provided by the government of Japan. UNESCO also provides two or three "experts" each year, usually seismologists and earthquake engineers from outside Japan. The institute conducts regular lecture and laboratory courses, as do the visiting lecturers.

An average of some twenty students a year have been trained at the institute. Over the years, they have come from more than forty countries, including developing countries in Asia, Africa, South America and the Pacific region. Stipends have been provided by the government of Japan and through the UNDP Special Fund.

During 1963–68, the institute concentrated on routine training. The programme has now been extended to include an advanced course in which the emphasis is on research training. The students, some five a year, have previously been PhD graduates or hold equivalent qualifications. The advanced students assist in the lecturing programme.

The institute has a special role in fostering seismology and earthquake engineering in developing countries, where there is an urgent need both to mitigate the effects of earthquake disasters and to fill conspicuous gaps in the global recording of earthquakes.

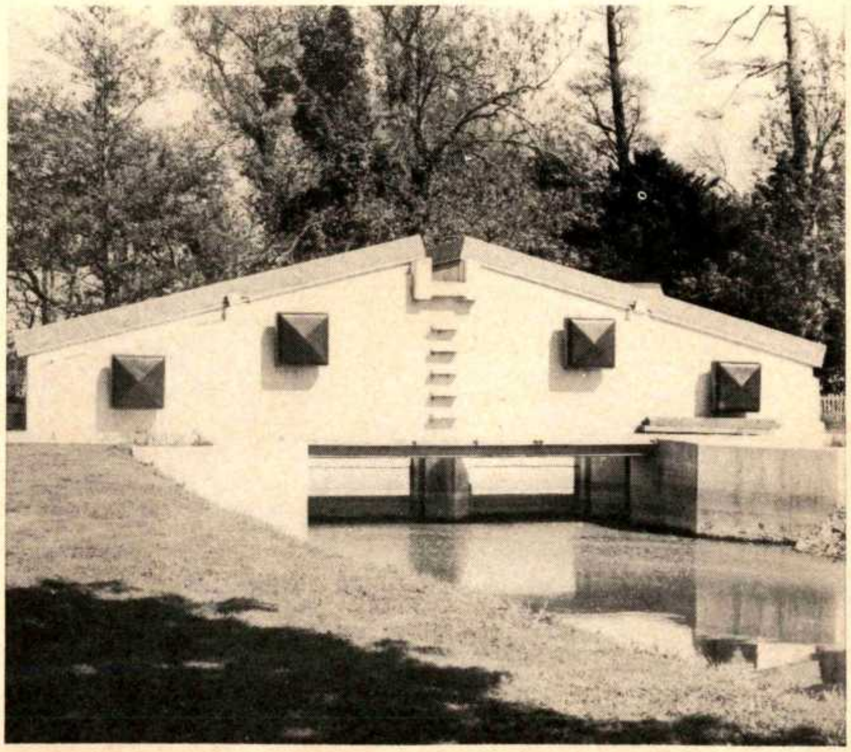
ASTRONOMY

South African Debate

EMOTIONS are still running high at the closing of the only strictly South African observatory, the Republic Observatory at Johannesburg. There have been bitter exchanges in the correspondence columns of *Monthly Notes of the Astronomical Society of South Africa*. The British Science Research Council is involved to the extent that the rationalization of South African astronomy was stimulated by the review of astronomy in the southern hemisphere completed late in 1968 by

Freshwater Biology

THIS is a fluvarium which was opened on July 23, together with other extensions, at the site of the River Laboratory of the Freshwater Biological Association in East Stoke, Dorset. The fluvarium, which was opened by Mr Peter Walker, Secretary of State for the Environment, has been so called because it is an aquarium in which the tanks contain flowing water. Built where once a corn mill stood, the building is a water-tight concrete box, 30 feet by 12 feet, sunk 9 feet into the ground. The roof is made of glass, and the flow of water through the fluvarium is maintained by gravity, without recourse to pumps.



a committee of four set up by the council.

Like the more recent review of astronomy in the northern hemisphere (see *Nature*, **232**, 289; 1971) the report of the southern hemisphere review committee was never published. But it is understood that the committee was particularly concerned with the reduction of British commitments in South Africa with the building of the Anglo-Australia 150-inch telescope.

As a part of this plan, the Royal Observatory at the Cape of Good Hope, which has been in the hands of the Science Research Council since 1965, is to be run as a joint venture with the South African Council for Scientific and Industrial Research. At the end of this year, the Royal Observatory at the Cape will become the headquarters of what is to be known as the South African Astronomical Observatory, having as its first director Sir Richard Woolley who retires as Astronomer Royal at the end of the year. The chief facilities of the observatory, however, will not be at Cape Town, where of course city lights have long been a problem, but at a new site which is being established 235 miles to the north-east at Sutherland.

It is understood that the British contribution will be of the order of R1 million over ten years, compared with R2 million from the CSIR over the same period, and that the CSIR will have the controlling interest.

What some astronomers in South Africa and elsewhere are objecting to is that the rationalization of South African astronomy also involves the closing by the CSIR of the observatory at Johannesburg. The most vociferous support for keeping the Republic Observatory comes from Dr W. S. Finsen, who was director from 1956 (when the observatory was known as the Union Observatory) to 1965, and Dr W. H. van den Bos, director from 1941 to 1956. But Drs Finsen and van den Bos are being encouraged in their campaign by astronomers outside South Africa. Among others, Drs A. F. Cook and B. G. Marsden of the Smithsonian Astrophysical Observatory have expressed their concern about the future of long-term programmes on the positions of asteroids and on double stars at present being carried out by the Republic Observatory.

The reaction of the CSIR is that omelettes cannot be made without breaking eggs. Unfortunately, however, the continuing debate between the opposing factions is being conducted at an acrimonious and personal level, in *Monthly Notes* as well as in the Johannesburg newspapers.

Among the concerns of Drs van den Bos and Finsen seem to be that the new arrangements will put the centre of gravity of South African astronomy in the Cape Town area. They are suspicious that the role of the Royal Observatory at the Cape as the headquarters of the new observatory was decided before the location of the new observing site was chosen, rather than the sequence of events presented by the CSIR in which the site at Sutherland was chosen first, after which the selection of the Royal Observatory as headquarters became obvious because of its proximity. But Drs van den Bos and Finsen also dispute the choice of Sutherland because its "bleak and isolated locality" (on the western edge of the Karroo) will not be attractive to observers, because of their argument that the programmes on asteroids and double planets would not benefit from being transferred to Sutherland from Johannesburg and because of their claim that South Africa contains better sites than Sutherland.

The CSIR case has been put by Dr F. J. Hewitt, chairman of the South African National Committee on Astronomy and vice-president of the CSIR. He says that the Sutherland site was selected on its merits, that the choice of the Royal Observatory as headquarters then became logical, that the Republic Observatory is in any case run down, and that "a particularly unfortunate aspect has been the attempt to involve astronomers overseas in the campaign against these new proposals".

Particularly galling to Drs van den Bos and Finsen is that the CSIR did not appoint a new director to the Republic Observatory after Dr Finsen's retirement. Since then the observatory has been making do with an acting director, Mr J. Hers.

It is regrettable that the debate is taking place only after the decision on the South African Astronomical Observatory was announced by the CSIR on September 23 last year. As things stand, the efforts of Drs van den Bos and Finsen are in danger of being regarded as a lost cause being conducted by the old guard of South African astronomers reluctant to be moved from Johannesburg. Nevertheless, since the CSIR took over the running of the Republic Observatory from the South African Government in 1964, the CSIR has had the responsibility of seeing that rearrangements are made only after proper consultation, an obligation which Drs van den Bos and Finsen would say has not been carried out.

Meanwhile, it appears that the 26½-inch refractor at the Republic Observatory—the largest instrument and about fifty years old—is likely to continue in operation at Johannesburg for two or three years more. The observatory Franklin-Adams used for work on asteroids and comets at a site 50 miles outside Johannesburg is expected to remain where it is for a year or two. Discussions are going on about what to do with the other aspects of the work of the observatory—chiefly the maintenance of the national time service—and the observatory's library is being moved to Cape Town.

The rationalization now planned takes no account of the Radcliffe Observatory at Pretoria, which has in the past been financed by the British Science Research Council. For some time, the council has been saying that its support will end in 1974, and the Radcliffe Trustees, the formal owners of the observatory, would be hard pressed to know where to look for continued support. But the Radcliffe Observatory has a splendid 74-inch reflector, and the plans for the Sutherland site so far include no large telescope. Is it too much of a coincidence that 1974 would be a good time to move the Radcliffe instrument from Pretoria? And is there now a danger that that would be a further thorn in the flesh of the Afrikaaners on the Rand, ever suspicious of the Cape? After all, a site three-quarters of the way to the Cape does not seem like a no man's land even if it is mostly desert.

The consensus among astronomers is probably favourable towards the efforts by the CSIR to provide a strong centre for South African astronomy. In spite of several successes, astronomy in South Africa has not had the reputation that should have come to one of the few countries favourably placed to observe the relatively unexplored southern skies, which include the galactic centre and the Magellanic Clouds. The South African observatories have already been eclipsed by the observatories in Chile, where the United States and others are investing in the remarkably clear skies of the Andes.

Nevertheless, most astronomers will also wish that the CSIR had gone about its plan with more tact. And it is obviously important that some way should be found of continuing the long term programmes on the asteroids and double stars that are being carried out by the Republic Observatory.

SPACE POLICY

Black Arrow Scrapped

THE British Government has decided to end the Black Arrow satellite launcher programme. This is no surprise and indeed the decision has been foreshadowed on several occasions during the past few months especially in the evidence of the Ministry of Aviation Supply and the Department of Trade and Industry before Subcommittee B of the Select Committee on Science and Technology. It is nevertheless surprising that the government should have chosen to make its announcement only three months before the select committee is expected to publish its report and recommendations on the future of space research in Britain.

The Black Arrow rocket has been an integral part of the National Space Technology Programme for several years. Its end is a part of the review of the programme being carried out by Mr Frederick Corfield, Minister of Aerospace at the Department of Trade and Industry. The department has always argued that the programme should be oriented to achieve the best results for the smallest expenditure and with an eye on the need that British industry should gain technologically. At present, about £4.6 million a year is spent on the programme, about 20 per cent of the total for all British space activities (see Table). Of this total, about 55 per cent is spent on scientific research. The government evidently now feels that Black Arrow does not represent sufficiently good value for money. Some scientists had hoped that a British rocket would eventually be used to launch a British scientific satellite but that idea too dies with Black Arrow.

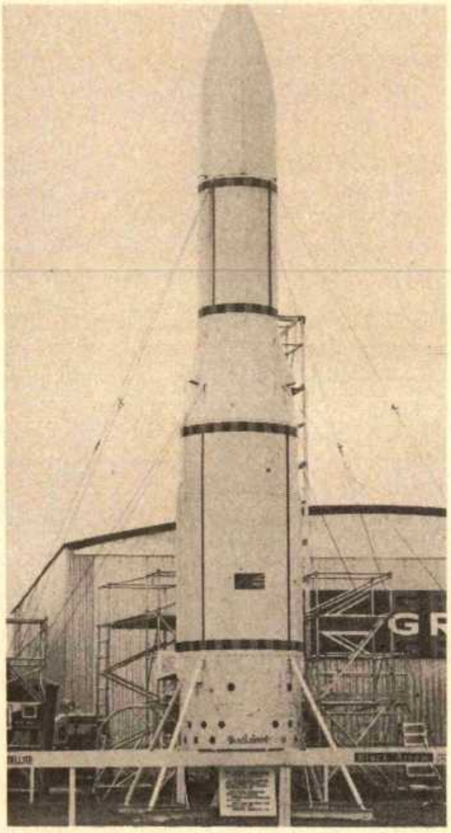
The X3 satellite due to be launched by Black Arrow in September.

The DTI seems to have convinced itself that there is very little expertise to be won from small satellites in the low level polar orbits which could be reached with Black Arrow. Nowadays, interest centres on satellites in geostationary orbits. The next launch of Black Arrow, with the X3 satellite, from Woomera during September will be the last. The planned X4 satellite will be launched from the United States on a Scout rocket.

British Space Expenditure, 1970-71 (£000 estimated)

International	
ELDO	£1,840
ESRO	£5,450
Intelsat	£1,130
Post-Apollo studies	£230
National	
Defence	£6,730
Commercial satellite communications (Post Office earth terminals)	£1,600
Scientific space research	£3,930
National Space Technology Programme	£4,640
Total	£25,550

Apart from being limited in capacity, Black Arrow is neither dependable nor cheap even allowing for the long intervals between launches, which have meant that it has never been fully tested. During the six years of development from the Black Knight rocket, £11.5 million has been spent with each launching costing £2 million. One launch has failed, one has been a success and one a partial success. The total cost of a Scout launching will be about £1.25 million. The whole rather unsatisfactory situation was summed up by the companies involved in the manufacture of the satellite who advocated earlier in evidence to Subcommittee B that Black Arrow should be fired oftener or scrapped altogether.



The Black Arrow Rocket.

The government's plans for testing much larger satellites and complete applications systems in geostationary orbit are unlikely to be spelled out before the end of the year—almost certainly after the Select Committee has presented its report. But the X4 satellite will contain a prototype system for maintaining the triaxial stability which is vital for most applications satellites, particularly for those in geostationary orbits. The Thor Delta is the obvious launcher but would cost about £3.3 million a time.

The British Government seems to be talking as if there will be no difficulty in being able to use whichever American rockets appear best to suit its plans for launching satellites, but no formal agreement yet exists and this is a field in which private understandings are notoriously capable of being undermined by the ins and outs of governments. In the circumstances, it would not be surprising if the British Government might yet choose to collaborate in the construction of some rocket launcher within the framework of ELDO, although it is clear that many hearts would have to change before that became a painless operation.

The preliminary decisions taken last month by the council of ESRO to go ahead with a space applications programme as distinct from the scientific programme which has been ESRO's chief concern since its inception in 1962 must also have influenced the decision to scrap Black Arrow. Britain at present contributes about £5.5 million a year to ESRO (see Table) and this sum is likely to increase quite rapidly if the applications programme goes ahead smoothly. France, Germany, Italy and Britain have agreed to provide £33 million by the end of 1973 and then a minimum of £30 million a year until 1980. It must have become clear to the DTI that if British industry is to contribute in a significant way to a European applications programme and thus provide some economic feedback for the money invested in ESRO, it must gain the expertise with geostationary systems that could not be properly attained with satellites launched by Black Arrow.

The increasing involvement of the DTI with ESRO also means that the department will take on an increasing share of the representation of the UK at ESRO. At present the Department of Education and Science provides most of the representatives although it is advised by members of the Department of Trade and Industry.

One of the unresolved questions is that of British or European participation in the post-Apollo programme which still suffers from lack of definition and whose very existence seems doubtful. One of the suggestions which the United States Government made last year was that Europe should contribute "at least 10 per cent" towards the development of the post-Apollo transportation system whose total development cost would be "about £4,000 million" during the next ten years. It has been suggested, for example, that agreement to join the post-Apollo programme could pave the way for NASA to launch European applications satellites and presumably UK payloads of the same type as well.

NEW WORLD

Davis Committee Exposes the Problems

by our Washington Correspondent

THOSE who believe that the United States has a workable and explicit policy for the support of research and development had only to attend three meetings last week of the Science, Research and Development Subcommittee of the House Committee on Science and Astronautics to discover that their faith may be groundless. The subcommittee, under the chairmanship of Mr John Davis, took a speculative bite at a problem that will keep it occupied throughout the autumn and winter, but which could well require many more years of probing before worthwhile conclusions can be formed. The subject that the committee intends to study is "science, technology and the economy"; whether the committee has bitten off more than it can chew remains to be seen. Nevertheless, to judge by what the hearings uncovered last week, the subcommittee could do a valuable job in bringing even some of the more obvious problems to public attention.

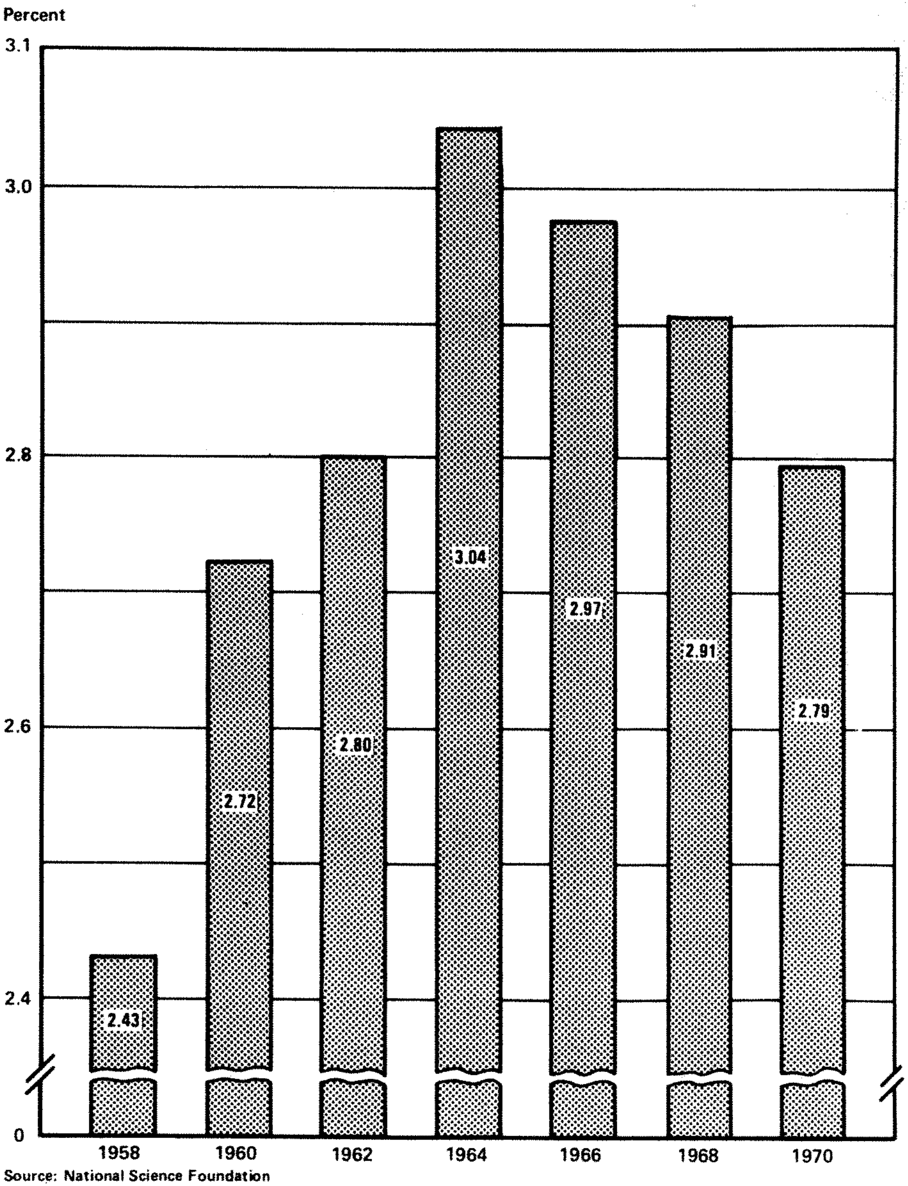
Chief among the factors that will occupy the committee's attention is that the growth in expenditure on research and development in the United States has been decelerating during the past decade. During the past five years, for example, expenditure on research and development has been growing at only 0.3 per cent a year taking inflation into account, compared with a real growth rate of about 11 per cent in the late 1950s. It seems that what is most at fault is the mechanism for promoting research and development in the private sector.

What policies are needed to ensure that more funding for research and development will stimulate the flagging economy of the United States, and reverse the slide in the nation's trade balance? According to the American Federation of Labor and Congress of Industrial Organizations (AFL-CIO), the answer may be found in simply imposing federal restrictions on the outflow of capital and technology from the United States.

The theme of the AFL-CIO's argument, presented to the subcommittee by Mr Andrew J. Biemiller, a former congressman, is that uncontrolled foreign investment has enabled other nations to match the technology of the United States in some crucial areas. The upshot is that United States capital has stimulated other nations' economies and has provided job opportunities abroad, while unemployment in the United States has steadily been getting worse. In short, the AFL-CIO accused the United States of exporting technology at the expense of home investment. Citing the textile industry as an example, Mr Biemiller pointed out that Asian textiles were no threat to the American market at one time because they could be relied on to shrink, but that situation was changed when the sanforization process was licensed outside America.

Economic isolationism is, however, unlikely to find many friends in Congress, and the AFL-CIO was given a fairly rough ride by the committee and by Murray L. Weidenbaum, assistant secretary to the Treasury for economic policy, at a later hearing. Referring to the ideas as "crude protectionism", Mr Weidenbaum said, "one thing you don't do is to prevent the international movement of technology or inhibit licensing in that way". He pointed out in particular that the international flow of technology is a two-way process, and that the United States is also at the receiving end of some foreign technologies.

Mr Weidenbaum's own suggestion is that "what is needed is a relatively steady trend of funding for research—steady in 'real' terms to protect research budgets against the inroads of inflation". But, while it is relatively easy to plan the rate of funding for research and development in the public sector, the private sector is a much tougher nut to crack. And the impor-



Source: National Science Foundation

The ratio of expenditure on research and development to the gross national product, 1958–1970.

tance of providing sufficient incentives for research and development in the private sector is emphasized by the fact that about 85 per cent of the development part of R & D is performed by private industry, chiefly with financial support from the companies themselves.

Maurice H. Stans, Secretary of Commerce, left the subcommittee with a few suggestions to chew over, however. "We should examine," he said, "the feasibility of establishing a single federal focus for several activities directly related to enhancement, assessment, and forecasting of industrial technology." This suggestion is an echo of an old cause of the subcommittee's, which held a number of hearings last year under the former chairman, Emilio Q. Daddario, to explore the feasibility of setting up an Office of Technology Assessment, and which has recently been putting that into effect.

The second option suggested by Mr Stans is that the committee should carefully consider the feasibility of creating direct or indirect financial incentives to stimulate new technology. Federal assistance could be provided to private companies—for example by loan guarantees, cost sharing, grants or procurement incentives, and the risk of setting off to develop a new technology could also be offset to some extent by tampering with the tax structure, giving depreciation allowances, and a host of other indirect subsidies. And, taking a sideways glance at his own National Bureau of Standards, Mr Stans suggested that there could be considerable tightening up on the setting of industrial standards. "Potential manufacturers," he said, "hesitate to invest heavily in the introduction of innovative equipment when they are uncertain about the requirements or specifications which will define the market for such equipment, especially in export trade."

But voluntary standards made by private industry are likely to fall foul of the anti-trust laws. Although the overt reason for the anti-trust laws is to prevent the formation of cartels and similar price-fixing rings, they can also have the effect of slowing research and development, for with the exception of a few special cases it is illegal for companies to collaborate on research projects. Mr Stans suggested that "it may well be time to modernize the anti-trust laws which evolved to deal with the different problems of an earlier era in order to permit the pooling of funds and risks that must accompany major technological advances". He was also quick to point out when questioned by the committee that it is premature to draw the conclusion that changes in the laws are on the way. Nevertheless, it seems clear that in areas such as research and development on pollution control, some relaxing of the anti-trust laws is being considered at least in the Department of Commerce.

Mr Stans told the subcommittee that in some areas American companies are being hamstrung by the anti-trust laws in such a way that they find it difficult to compete on equal terms with joint research projects conducted by their foreign competitors. But at home the anti-trust laws are increasingly becoming a source of concern for the smaller motor manufacturers who must meet stringent exhaust emission standards by 1975.

Mr Leonard Woodcock, president of the International Union, United Automobile, Aerospace and Agricultural Implement Workers of America (the union which represents most of the motor workers in the United States), wrote to Mr John N. Mitchell, the Attorney General, on May 24 suggesting that unless a crash programme combining the resources of all manufacturers in the automobile industry is conducted, the problem of exhaust pollution may not be solved before the 1975 deadline, and moreover, many of the smaller automobile companies are likely to go to the wall simply because they have insufficient funds to invest in pollution research. "This cooperative effort," he said, "can be maintained within both the spirit and the letter of our anti-trust laws." But Mr Richard McLaren, Assistant Attorney General in the Anti-trust Division, did not agree, for in reply to Woodcock's letter he said "we cannot agree . . . with your statement that there should not be competition in such vital areas as human safety and pollution control. Competition has served us well as a spur to the enormous technological gains achieved in this and previous decades. It should not be abandoned as we strive to meet the critical challenges to the safety and health of American citizens".

Perhaps the best explanation of the policy of the Department of Justice towards collaboration on pollution research was given by Mr McLaren in a letter to Mr John A. Volpe at the Department of Transportation, when he said "the Department of Justice feels that government agencies which are charged with the responsibility of meeting specific public goals, such as promoting automobile safety, should proceed in a manner which promotes competition to a maximum extent consistent with the achievement of their specific statutory responsibilities". Obsolete or not, the anti-trust laws are plainly a fundamental part of the American industrial ethos.

Pesticides in the Open

A MUCH criticized obstacle to the free flow of scientific information about pesticides and herbicides was removed last week by Mr William D. Ruckelshaus, Administrator of the Environmental Protection Agency. The EPA has now decided to release scientific advisory reports on controversial pesticides as soon as it receives them. The reports, which often constitute an important part of the mechanism by which an allegedly dangerous agent is banned or allowed for use, have in the past been kept secret until a final decision is taken. This has made it impossible for the scientific information contained in the reports to be criticized or discussed by professional scientists until it is too late to affect the final decision.

The scientific advisory reports are filed under the provisions of the Federal Insecticide, Fungicide and Rodenticide Act, which allows a manufacturer of a product whose use has been cancelled by the EPA to request that the issue be referred to an advisory committee or to ask for a public hearing. This procedure can delay cancellation by six months or more, for the manufacturer has 30 days after the serving of a cancellation notice to request referral to the advisory committee and the committee, whose members are nominated by the National Academy of Sciences, has 60 days in which to make its report. Within 90 days, Mr Ruckelshaus must then decide either to confirm or to set aside his earlier notice of intention to cancel or suspend the product. During the whole of these proceedings, the manufacturer is allowed to market the product.

The issue of secrecy has been brought into sharp focus recently with the controversy surrounding a report on the herbicide 2,4,5-T, which was submitted to Ruckelshaus in May. A few copies of this have found their way into circulation, and it has come in for strong criticism from some sectors of the scientific community. One of the charges levelled at the report is that the scientific information which it contains would not be acceptable for publication in a scientific journal, because some of it is based on superficial experiments conducted without proper controls. That information will, however, now be open to criticism, for the 2,4,5-T report is available from the EPA upon request.

ATOMIC ENERGY

Seaborg to Leave AEC

by our Washington Correspondent

DR GLENN T. SEABORG, chairman of the Atomic Energy Commission for the past decade, will leave the AEC next year, probably in November, to return to the University of California at Berkeley. His resignation, which was announced recently, was obviously expected in the White House, for President Nixon wasted little time in making public his choice for a successor, and sent the name of James R. Schlesinger, an assistant director of the Office of Management and Budget and a lifelong Republican, to the Senate for approval. Seaborg pointed out in his letter of resignation that last year he expressed the desire to return to California to resume his research on transuranium elements—research for which he won the Nobel Prize in 1951.

Although Nixon accepted Seaborg's resignation "with regret", and was unstinting in his praise for Seaborg's record of achievements at the AEC, it has been suggested that he was looking for a change of leadership for the commission. During the past year, the AEC's nuclear energy programme has faced mounting opposition from environmentalists, and strong doubts have been cast on its nuclear safety programme. Nevertheless, Seaborg has skilfully ensured that the AEC's programme has gone forward largely unmodified, and there is little doubt that he has served the commission well during his ten years in office.

Seaborg is the president-elect of the American Association for the Advancement of Science, a position to which he was elected last December in the face of considerable opposition from some members of the association. The chief complaint raised against his candidacy was that as head of a much criticized government agency, he would find a conflict of interest in many of the issues with which the AAAS is involved—the issue of reactor safety which the AAAS was asked by Senator Edmund Muskie to investigate, for example. Few, however, opposed his election on personal grounds, and his resignation from the AEC may help to assuage those fears, although for the major part of his term of office at the AAAS, which starts on January 1, 1972, he will be wearing both hats.

Schlesinger, Seaborg's proposed successor, is widely regarded as a whiz kid in the Nixon Administration. A graduate in economics from Harvard, where he later obtained a PhD, he has been a member of the faculty of the University of Virginia, and immediately before joining the Nixon Administration in 1969 he was engaged on a study of nuclear proliferation at the Rand Corporation. His first and only job in the Administration was in the old Bureau of the Budget and later in the Office of Management and Budget, where his chief area of concern has been defence spending, but he has also been involved with funding for environmental protection. He was also said to have been considered by Nixon for the post of Under Secretary for the Interior, but that suggestion was opposed by Republicans from the Western States, and his name was never put forward for nomination.

Environmentalists will be able to take some heart from the fact that his hobby is bird-watching. But as head of the AEC he will face a difficult task in resolving the conflict between environmentalists who oppose the nuclear power programme and the strong advocates of nuclear energy in the Congress and the Administration. Nixon will be looking to Schlesinger to put into effect the commitment to have a liquid metal fast breeder reactor in operation by 1980—an important part of the message to Congress in June in which Nixon requested $3,000 million for a crash programme for developing clean energy. The decision to concentrate on nuclear power production at the expense of other possible fuels has met with considerable opposition from environmentalist groups, who are urging a closer scrutiny of the environmental and public health hazards from reactors. Schlesinger's job at the AEC will evidently be to make sure that the nuclear power programme is not seriously disturbed by such fears, although he must obviously satisfy his critics that he is not deaf to their warnings.

James R. Schlesinger, Nixon's nominee as AEC chairman.

Uranium Enrichment

A FUNDAMENTAL change of policy for the sharing of information on uranium enrichment was announced last week by the US Atomic Energy Commission. The AEC is prepared to enter into discussions with the governments of ten other nations to explore possibilities for cooperating in multinational uranium enrichment facilities. The AEC is quick to point out, however, that these talks "would not involve a commitment at this time on the part of the US to make such technology available for use abroad". The talks are therefore simply concerned with exploring the financial and security arrangements under which the United States may be prepared to grant licences for the operation of gaseous diffusion plants in foreign countries. The nations to be represented at the talks are Britain, France, West Germany, Holland, Belgium, Luxembourg, Italy, Australia, Canada and Japan.

The Joint Committee on Atomic Energy has long opposed any move towards the sharing of American gaseous diffusion technology with other nations, chiefly because it fears that the technological and economic lead that the United States now holds in this process may be lost, and some members clearly view the announcement with misgivings, for the committee has asked in no uncertain terms to be kept informed of developments. The commitment to enter exploratory talks is the fruit of a review of US policy on uranium enrichment conducted by the administration and announced by President Nixon in his foreign policy report to Congress on February 25.

The Atomic Energy Commission also points out that gas centrifuge technology will not form a part of the exploratory talks, so that the United States is not seeking to join Britain, West Germany and Holland in their multinational research effort on the gas centrifuge process (see page 360). An official at the AEC pointed out that the talks will be limited to gaseous diffusion because that process has already been proven, and it offers the best approach to meeting the demand for enriched uranium in the late 1970s.

This change in policy is bound to be welcomed by the nations involved, as it will expedite the use of uranium for peaceful purposes.

NEWS AND VIEWS

New Baskets for Old

UNICELLULAR organisms reflect the extremes to which cellular morphogenesis can be stretched, as any protozoologist will testify. However esoteric their appearance they also retain the ability for clonal growth—to generate repeatedly two "finished" cells from one. They, and indeed most cells, contain organelles made up of microtubules—arrays of globular protein subunits which form hollow tubes of diameters around 250 Å. Protozoa should therefore spell out the range of possible structures which can be formed from microtubules and yet be reduplicated in a spatially precise manner at each cell division. The control of such a system presents intriguing problems. On page 387 of this issue of *Nature* J. B. Tucker of the University of St Andrews, Scotland, raises questions about the spatial discrimination that must underlie the formation of microtubular components in the ciliated protozoan *Nassula.*

The largest organelle in *Nassula* is the feeding apparatus the pharyngeal basket), a palisade of rods made up from longitudinal microtubules and attached to the cell surface. At division the old basket detaches from the surface and two new ones appear. Each new rod begins its assembly close to a basal body, another and more ubiquitous microtubular structure. The rods first appear in short rows; they align and detach from the basal bodies and then roll up to constitute the circular palisade. The completed baskets make microtubular connexions to other surface basal bodies. The two new baskets do not always include all the new rods, and these "errant" rods, after moving away, break down as do the old rods, while the integrated new rods elongate by addition of microtubular protein to their tips. How can rods in one area of the cell add subunits while apparently identical rods elsewhere in the same cytoplasm are being dismantled?

Like flagella elongation in *Chlamydomonas* the synthesis and assembly of rod microtubules are separable events. Cycloheximide inhibits synthesis and colchicine blocks assembly. Errant rods do not move away from the new baskets in the presence of vinblastine, nor are they resorbed, although the old rods continue to break down. Tucker erects two alternative hypotheses to explain this effect. Further research relevant to this study will be the resolution of the number of different types of microtubule subunit involved, and whether the microtubular assemblies appearing at different times and in different places are composed of identical subunits, and if so whether these share a common subunit pool, and are recycled when the structures are broken down.

The questions that Tucker raises—how the subunits are localized at the points of assembly and whether random diffusion of subunits synthesized throughout the cell accounts sufficiently for the observations—are two among several problems. They include the nature of the information system specifying the location of "nucleation" centres for organelles, the number of such centres and the regulation of the dimensions of the realized structures, and the self-assembly properties of the subunits. Tucker has previously observed in living cells that rod length fluctuates with feeding and starvation and that when the number of developing tubules is reduced they reach greater than normal length; both these facts are consistent with the available subunits determining the length. Dingle can upset the control of flagella number in *Naegleria* by heat shock at the moment of amoeboid-flagellate transformation (*J. Cell Sci.*, **7**, 463 ; 1970). The attraction of this system is that high developmental synchrony can be obtained in populations of these amoebae. Tilney (*Devel.* Biol., **2** (Suppl.), 63 ; 1968) and Roth (*J. Ultrastr. Res.*, **30**, 7 ; 1970) have suggested that the pattern of microtubules in the axopod of the heliozoan *Echinosphaerium* is a function of cross-linkages of fixed length and orientation between tubules rather than of an "orientation centre". Heat-shock disruption of rod tubules in *Nassula* and the subsequent abnormal arrangements of tubules argue in favour of the initiating sites as the determinants of the final pattern.

The solution of these problems promises to be of interest to all cell biologists and it may in addition shed light on the phenomenon of "cortical inheritance" in ciliates—alternative patterns of the same microtubular structures existing stably over hundreds of cell divisions in the absence of gene differences. Finally, it would be a glaring omission not to point out the close affinity in interest and attack between this field and that of phage morphogenesis (Levine, *Ann. Rev. Gen.*, **3**, 323 ; 1969).

Filling the Dating Gap

THE dating of the earlier part of the Pleistocene period still presents considerable problems but further exploitation of the various "radioactive clocks" should eventually overcome these difficulties. It is particularly encouraging that thermoluminescence dating may soon be extended to date bones and teeth from archaelogical deposits (Christodoulides and Fremlin, *Nature*, **232**, 257 ; 1971). The use of this method is well established for the dating of baked clay obects, and its potential for solving questions of authenticity has been illustrated in the past week by Martin Aitken and his colleagues at the University of Oxford who have demonstrated clearly that some "Etruscan" wall paintings on terracotta in European and American museums are at the most 12 years old (Aitken *et al.*, *Archaeometry*, **13**, 89 ; 971 ; Fleming *et al.*, *ibid.*, 143).

The promise of the thermoluminescence dating method of Christodoulides and Fremlin is that it will span the gap which still separates the time range of radiocarbon dating and the clocks of longer half-life. At the early end of the human time scale, potassium-argon dating has been useful in establishing a chronology for artefacts or hominid remains. The youngest dates obtainable from the uranium-lead and rubidium-strontium methods are about 10 million years, so that these isotopes, which are useful for longer geological time spans are not helpful here. The half-life of ^{40}K is 1.03×10^9 yr, however and mass spectrometry allows the determination of one of its decay products, the gas ^{40}Ar, in low concentrations. It is more difficult to date more recent ages than older ones because of the small quantities of argon involved, and the lower limit of the method is at present half a million years or a little less.

At the other end of the scale is radiocarbon dating. Radiocarbon dates now provide the essential basis for prehistoric chronology from Upper Palaeolithic times on and, until recently, radiocarbon seemed the most reliable of radioactive clocks. For a radioactivity-based age determination, it is usually necessary, of course, both to measure the quantity of the decay product present and the quantity left of the parent isotope. Radiocarbon dating was able to dispense with the former, because the original concentration of the parent isotope, ^{14}C, was assumed to be the same as the modern atmospheric concentration. The discovery that the atmospheric concentration of ^{14}C has fluctuated in recent millennia by up to 8 per cent of the present level has come therefore as something of a shock. The radiocarbon determination of dendrochronologically dated samples is now allowing the investigation of this effect back to 6000 BC, but its magnitude before this time remains uncertain.

The half-life of radiocarbon, approximately 5.7×10^3 yr, sets a more fundamental limitation on the age of samples which can be dated. The short half-life means that after a few tens of millennia there is very little radioactivity left in the specimen, and the counting of disintegrations in the sample is always complicated by a background activity caused by cosmic radiation which cannot be eliminated. Even the isotopic enrichment of gas samples only increases the effective time range of the method to a maximum of 70,000 yr.

Between the potassium-argon and radiocarbon dating methods lies a gap from 50,000 to 500,000 yr where other methods are required. Fission track dating is a possibility, especially when applied to volcanic glass. But like the potassium-argon method it gives the date of formation of the rocks under examination so that for more recent times, where the archaeological remains are not likely to be interstratified with eruptive deposits, this is a serious limitation. It is over this time range that thermoluminescence dating would be most useful.

Thermoluminescence dating depends on the principle that many minerals give off light when heated—the light emitted being proportional to the radiation dose experienced since the formation of the material. Archaeologically it has so far been principally applied to pottery and baked clay and the dating involves determining the radiogenic minerals in the clay as well as the thermoluminescence itself. The necessity of determining very small quantities of decay product (as in the potassium-argon method) or of the parent isotope (as in the radiocarbon method) is thus avoided. An early problem was how to eliminate light during the readout on heating, which derived from the energy used in pulverizing the sample. Fortunately, heating in an atmosphere of nitrogen considerably reduces this problem. Further improvement of this method came from the separation of different grain sizes in the pottery and an accuracy of less than 10 per cent is claimed for fine grain dating (Zimmerman, *Archaeometry*, **13**, 29; 1971).

Until recently the chief application of thermoluminescence dating has been in testing the authenticity of museum objects. The magnitude of the variations in atmospheric concentration of ^{14}C, suggested by tree-ring work, indicated a further useful line of approach, and the first TL results of Zimmerman and Huxtable on early neolithic pottery from the Balkans (*Antiquity*, **44**, 304; 1970) lend some support to the long chronology indicated by tree-ring work. Pottery was unfortunately not manufactured before about 7000 BC, but the same authors have dated baked clay figurines from the Gravettian site of Dolni Vestonice to 33,000 BP (*Archaeometry*, **13**, 57; 1971). The thermoluminescence age is 15 per cent higher than the radiocarbon age, with a probable error of 10 per cent. The method thus offers a useful check on radiocarbon dates.

The materials most readily available from Palaeolithic deposits are flint and bone, and it is these which make the work reported by Christodoulides and Fremlin, and the work which is currently in progress on thermoluminescence dating of flint, so promising. Once again the chief problem is luminescence arising independently of the radiogenic thermoluminescence which is to be measured. Christodoulides and Fremlin have reduced this effect to the extent that useful measurements can now be made on samples older than 100,000 yr.

If further work succeeds in reducing this background thermoluminescence by another order of magnitude, the method may yet yield useful dates in, and beyond, the 8,000 to 50,000 yr range at present covered by radiocarbon dating, but not yet checked by dendrochronology.

Mechanism of Polarity in Dispute

THE mechanism of genetic polarity has of late become the centre of one of those controversies which occasionally enliven the literature and the coffee room. One camp holds that nonsense codons, by stopping the movement of ribosomes translating nascent messenger RNA molecules, prevent further transcription because transcription is coupled to translation. Members of the other camp argue, however, that nascent messenger RNA chains continue to be elongated after a nonsense codon at some early position has prevented ribosomes translating the messenger. They claim that because the newly made stretches of messenger are devoid of ribosomes they are rendered susceptible to attack by nucleases and are degraded.

In next Wednesday's *Nature New Biology* there are two articles which present conflicting data to succour members of both camps. Imamoto and Kano, who favour the first hypothesis, have studied the synthesis of *tryp* operon mRNA in a strain of *Escherichia coli* with a temperature sensitive mutation in the structural gene for one of the 30S ribosome proteins, P10, which must be present for ribosomes to initiate translation of natural messengers. They present evidence which suggests that the overall rate of transcription of the *tryp* operon in this strain parallels the rate of protein synthesis. At the nonpermissive temperature protein synthesis is impaired and correlated with this synthesis of *tryp* messenger RNA is arrested.

By contrast, a few weeks ago Morse and his colleagues reported in *Nature New Biology* (**231**, 214; 1971) experiments which suggest that messengers devoid of ribosomes are degraded by a previously undetected endonuclease. Morse and Guertin now report new experiments on the effect of starving *E. coli* of amino-acids on the polarity of polar nonsense mutations in the *tryp* operon. Polarity is relieved when stringent cells carrying such mutations are starved; in other words, the *tryp* mRNA distal to the polar nonsense mutation, which is rapidly degraded in the presence of an adequate supply of amino-acids is stabilized when amino-acids are in short supply. By contrast, when relaxed strains are similarly starved there is no relief of polarity; indeed polarity is enhanced.

Morse and Guertin suggest that because starvation of stringent cells results in the cessation of ribosomal RNA synthesis as well as protein synthesis nucleotides must accumulate, and this might well result, by some feedback control mechanism, in the inactivation of nucleases. Messengers although exposed might therefore survive. By contrast, when relaxed cells are starved ribosomal RNA synthesis continues even though protein synthesis is halted.

HISTORY OF BIOLOGY

A "Non-event"

from a Correspondent

IT is a truth of history and an aspect of human behaviour that momentous occasions recalled in later life by men who took part often gain in grandeur and importance with the passing of time. A study of contemporary documents by J. W. T. Moody (*J. Soc. Bibliog. Nat Hist.*, **5**, 474 ; 1971) shows that the presentation of the Darwin–Wallace papers on natural selection to the scientific world on July 1, 1858, was no exception to this general rule. As Moody points out the occasion has been said to represent the beginning of a new era in scientific thinking—the beginning of modern biology or the Darwinian Revolution—but at the time of its presentation it was something of a non-event.

In the first place, the meeting at the Linnean Society at the critical day had been specially called by the president for the election of a new council member, but the opportunity was taken to deal with other business. A list of donations to the society's library and museum was read and there followed the election of the new councillor by ballot and a lengthy eulogy of the recently deceased vice-president, Robert Brown. Then the secretary read the text of the Darwin and Wallace papers on the laws which affect the production of varieties, races and species with an introductory letter from Sir Charles Lyell and Dr J. D. Hooker, and he followed by reading five other papers on miscellaneous and unrelated subjects.

According to the account of the event recollected by Hooker at the jubilee celebrations in 1908, only Darwin, Lyell, and Hooker himself, had any knowledge of the papers to be presented and Darwin for domestic reasons did not attend the meeting. Gage has noted (*A History of the Linnean Society of London*, 54; 1938) that at that date agenda were not sent to members, so the fewer than thirty members who attended the meeting can hardly have expected a momentous meeting. Hooker seems to have been the source of the impression that the audience was awed by the revelations read to them; in a letter thirty years after the event he wrote "the interest excited was intense . . . it was talked over after the meeting 'with bated breath'. Lyell's approval, and perhaps in a small way mine . . . rather overawed those Fellows who would otherwise have flown out against the doctrine . . .". Moody, however, suggests that the audience were not so much stunned by new ideas as they were overwhelmed by the sheer volume of information loaded upon them. No formal discussion took place at the meeting, the audience was expected to switch its attention instantly from the Darwin–Wallace papers to "Notes on the organization of *Phoronis hippocrepis*", and it is suggested that boredom and bewilderment on a July afternoon, as much as Lyell and Hooker's advocacy, contributed to the overawed silence which greeted the unveiling of the concept of natural selection.

GALAXIES

Circular Polarization

from a Correspondent

DURING the past two years astronomers have discovered circular polarization in the radiation from a variety of objects. At Jodrell Bank, for example, Conway and Gilbert measured significant circular polarization at 49 cm wavelength from several compact sources (*Nature*, **227**, 585 ; 1970), and a series of reports from Kemp and his colleagues has described the circular polarization in the light from white dwarf stars and planets (*Nature*, **232**, 151; 1971). The range of possible observations is now expanded still further with a terse announcement in *IAU Circular 2343* that circular polarization has been successfully detected in the optical radiation from two extragalactic sources.

For many years observers have determined the magnetic fields in the Sun by measuring the circularly polarized components in spectral lines split by the Zeeman effect. At the Crimean Astrophysical Observatory, Severny, Nikulin and Kuvshinov hooked up a modified solar magnetograph to their 100-inch reflector telescope, and monitored the light from the radio galaxy M87, quasar 3C 273 and a Seyfert galaxy NGC 4151. The condensed, superluminous nuclei in the last two objects gave a positive result: the degrees of circular polarization are 1.2±0.4 per cent for 3C 273 and 1.1±0.3 per cent for NGC 4151. One X-ray source in the galaxy Sco X–1 was also investigated, but like M87 it gave a negative result.

There are several ways of obtaining circularly polarized radiation, but theorists will understandably want to see a more detailed report before any firm conclusions can be drawn from this new discovery. It is important in that it adds another method for investigating physical processes inside remote compact objects. It is already well established that the synchrotron mechanism may be responsible for the continuum radiation at optical wavelengths, and with certain geometries for the magnetic field a circular component is also introduced into the radiation. An encouraging step in this direction is given by the 49 cm results, where the synchrotron theory seems to satisfy the observations.

SEAFLOOR SPREADING

Chemical Rates?

from our Geomagnetism Correspondent

SEAFLOOR spreading rates vary from ridge to ridge at any given time and probably even vary with time for any given ridge. The first of these propositions is easy to prove because the patterns of magnetic anomalies close to oceanic ridges may be compared directly with the well-dated geomagnetic polarity-time scale derived from continental rocks of the past 4 to 5 million years. When this is done it clearly emerges that average spreading rates for the past few million years are different for different ridges; and thus it is safe to say that current spreading rates are also different. Direct evidence for the

---

Dybbuks and Tachyons

A FEW years ago a suggestion was made that there might exist particles that travelled with a velocity greater than light. These particles, named tachyons, satisfy the fundamental equation of special relativity:

$$E^2-P^2=M^2$$

where E. P and M are the energy, momentum and mass of the particle. They differ, however, from ordinary particles in that their mass is imaginary but they have a real energy and momentum. In next Monday's *Nature Physical Science*, Raymond Fox of Haifa, Israel, points out that particles with imaginary mass, imaginary momentum and imaginary energy are also solutions of the fundamental equation, and Fox names such particles "dybbuks". The one important difference between tachyons and dybbuks is that whereas it has been argued that the concept of tachyons violates causality there is no likelihood of such a problem with dybbuks.

Fox gives a description of the possible interactions of these particles and applies the results to an evaluation of the gravitational interaction of a very dense star. An interesting prediction is that the gravitational radiation from a pulsar is very much less than presently estimated. Such a prediction is bound to arouse interest in astronomy circles and the basis of Fox's theory will no doubt be subject to intensive study.

second proposition is more tenuous, however, because it is difficult to assign ages beyond about 5 million years to either the continental reversal pattern or the series of oceanic magnetic anomalies. Nevertheless, although the uniform spreading rate is sometimes used as a working hypothesis in geophysics, there is now quite convincing evidence that spreading rates do vary with time.

The need to determine spreading rates as a function of time has led Bass (*Earth Planet. Sci. Lett.*, **11**, 18 ; 1971) to take the first steps in a novel approach to the problem. The point of his argument is that if it can be shown that the chemical composition of the basalt extruded at ridge crests varies systematically with spreading rate at the present time, then it might be possible to determine the relative spreading rates for older oceanic crust by chemical analysis. He has thus tried to demonstrate that such variations exist.

The first thing to be said about this approach is that there are known to be practical difficulties both in demonstrating composition–spreading rate correlations and, supposing such correlations exist, in extrapolating them to older rocks. It is an experimental fact, for example, that any dredge haul of basalt from the ocean floor is likely to contain more than one type of basalt. It thus becomes difficult to assign a particular chemical characteristic to any area, or even site, of the ocean floor. But even if this problem can be overcome by the selection and use of suitable criteria, the application of those criteria to older crustal basalts is likely to be invalidated by the possibility of secondary alteration. It is too soon to say whether or not alteration will ultimately prove to be an insurmountable objection to Bass's method; but Bass has, at least, been able to show that there are systematic relations between chemical composition and spreading rate although he admits that the data are "too sparse to establish a statistically compelling argument" for strong correlations.

The ridges Bass has chosen to examine are the rapidly spreading East Pacific Rise and Juan de Fuca Ridge, the moderately slowly spreading Gorda Ridge and the slowly spreading Mid-Atlantic Ridge. Not all samples from these ridges were accepted in defining the chemical characteristic for each ridge—several classes of rock which would have led to ambiguities in interpretation were excluded. But when the compositions of the rocks selected by Bass are plotted on the normative AN-OL-HY ternary diagram, systematic variations in the positions of the fields for the various ridges became apparent. Thus the fields for the ridges of lower spreading rate move progressively towards higher AN and OL values and the ends of the fields poorer in HY move progressively towards the AN corner. In short, the lower the spreading rate the richer in Al_2O_3 and the more undersaturated are the basalts.

According to Bass, the important conclusion to be drawn from these properties is that the lower the spreading rate for a ridge the greater is the depth from which magma can be derived. Thus if the maximum depth from which magma may be derived is, in effect, the maximum depth at which brittle fracture may occur, slowly spreading ridges must be underlain by thicker lithosphere. In other words, magma type or the chemical characteristics of the basalts may in principle be used as an alternative to seismic methods to determine the relative lithospheric thickness.

The correlation of lithospheric thickness with spreading rate then leads to conclusions about the processes which determine the maximum depth of brittle fracture. Whether the ridge is produced by stresses involved in the upwelling mantle material or by stresses imposed by the lithosphere sinking into trenches, the depth of brittle fracture (which determines the apparent thickness of the lithosphere) will increase with an increase in the rate of application of stress and thus with an increase in spreading rate. But working in the opposite sense is the effect of the geothermal gradient. The greater the spreading rate the greater will be the quantity of mantle material entering the ridge region from below and so the greater will be the heat flow. The higher geothermal gradient will effectively reduce the depth of brittle fracture. Although it is not possible to predict which of these processes will take precedence, Bass's correlation of the thickness-spreading rate in the lithosphere enables the relative effects of the two processes to be determined. Thus because increased spreading rates lead to thinner lithosphere it means that the geothermal gradient effect dominates.

HAEMOGLOBIN

Structural Variants

from our Molecular Biology Correspondent

SINCE Pauling's discovery rather more than twenty years ago of sickle-cell haemoglobin—the manifestation of what with unerring flair he dubbed a molecular disease—well over a hundred human haemoglobin variants have been documented. Some, but by no means all of these, are associated with pathological conditions, and a comparison of the stereochemical features of such species in the crystal with those of the normal protein should, one might hope, lead to a precise explanation of how a single-base mutation can encompass such dire physiological consequences. With the biochemical world still digesting the implications of his results on the relation between the structures of oxy- and deoxyhaemoglobin, Perutz, together with Greer, has recently embarked on

---

Uniaxially Reinforced Nylon Composites

IMPROVING the mechanical properties of polymers by inclusion of comparatively high strength and modulus fibres, such as glass or carbon, is well known. Unfortunately not all polymers are amenable to this method of reinforcement for, to utilize to the maximum the good mechanical properties of the fibres, the composite needs to contain long lengths of fibre. Any method of moulding such as by injection or extrusion, where there is drastic deformation and movement, will thus cause damage to induced fibres and so reduce their reinforcing effect.

The reinforced polymers which have had the greatest impact in engineering have therefore been constructed with thermosetting materials, such as epoxy and polyester resins, which require only simple "static" moulding conditions. The reinforcing fibres are placed in the mould with the desired orientation. Liquid resin is then added in the form of monomer or oligomer containing catalyst and the mould is heated. Polymerization then occurs and a solid moulding is formed. It is essential that no gaseous byproducts are produced during polymerization, for this causes disruption of the composite. Nylon is a well established engineering material which would benefit from fibre reinforcement. Some success has already been achieved by the incorporation of fibres before injection moulding, but fibre lengths in the composite are usually less than 1 mm and are almost randomly oriented.

Attempts to produce composites by this method of reinforcement fail because charging the mould with molten polymer is impracticable, and if normal monomers are used, water is evolved as steam during polymerization. But T. Bessell, D. Hull and J. B. Shortall report in next Monday's *Nature Physical Science* that this problem has been overcome by using caprolactam as the monomer and by inducing the ring opening type polymerization with anionic catalysts, so that the problem of gaseous byproducts is almost eliminated.

such studies of pathological variants (*Nature New Biology*, **230**, 261 ; 1971), and now Greer has contributed two new investigations of different types of structural aberration. To anybody except the young, the excessively blasé and the punch-drunk, they compel awe and fascination.

In the first article (*J. Mol. Biol.*, **59**, 99 ; 1971), Greer uses the difference Fourier method to study the structural effects of two different substitutions at a single position in the β-chain. Asn-102 is conserved in all known animal β-chain sequences, and may therefore be supposed to admit of little genetic tinkering. In haemoglobin Kansas, however, it is replaced by threonine, which causes the loss of cooperative function, and a decrease in oxygen affinity at physiological *p*H ; in haemoglobin Richmond it is replaced by lysine, without any clinical penalty.

The difference electron density map of deoxygenated Kansas shows a disturbance near the β-haem group, for the threonine causes crowding at a vinyl and methyl side chain. The haem is displaced, and with it the helix to which it is linked by way of the histidine iron ligand. This has other consequences, including a distortion at the interface of the α_1 and β_1 chains which affects even the α-chain structure at various points, including the haem surrounds. The threonine cannot fulfil one of the functions of the asparagine, of hydrogen bonding to an α-chain aspartate, and appears instead to form an intra-β-chain bond. In haemoglobin Richmond, the distortion of the structure under the influence of the substitution is much less, and the lysine is even able to bond to the α-chain aspartate. A consequence of one of the new contacts is to displace another arginine, which normally shows a prominent interaction with an α-chain tyrosine. Possibly for this reason the Richmond molecule dissociates much more readily than normal haemoglobin into dimers. In haemoglobin Kansas, in which an important saltbridge is absent, and the structure is generally distorted, this effect is still more pronounced.

Greer's second article (*ibid.*, 107) concerns itself with two haemoglobin M forms, Hyde Park and Iwate. The M variants are characterized by substitutions for haem-linked histidines, the corresponding haem groups being then inert with respect to oxygen, and normally in the ferric form. Haemoglobin Iwate has an α-chain substitution, and Hyde Park a β-chain, histidine being in both cases replaced by tyrosine. The chemistry of these forms shows many peculiarities—in one of them, for example, the isomorphous replacement by a mercurial occurs at the wrong thiol. The Hyde Park variant moreover has a tendency to shed its α-haem groups and in a proportion of the molecules in the crystal of the fully reduced pigment (and no doubt in solution) the haem is missing and its cavity is collapsed. The disturbance is localized, however, and is not transmitted to the rest of the molecule. Neither the aberrant tyrosine nor the distal histidine in this molecule approaches the haem.

In the α-chain Iwate variant the α-haem iron is evidently linked to the tyrosine and the normal distal histidine. The most striking feature of the structure in both the fully ferric and the β-deoxy-forms is that it is fixed in the deoxy-configuration, in spite of well-defined changes in the β-chain when its haem is liganded. This rationalizes the striking difference between the two M variants, Hyde Park having both normal oxygen affinity in its functional haems and a Bohr effect, and Iwate a low oxygen affinity and no Bohr effect. Evidently the tyrosine-iron bond prevents the normal steric transition to a state favouring the transition to the high-affinity quaternary structure, which, one may infer, originates in the α-chains. Molecular pathology aside, the particular value of these studies, especially when details can be seen at higher resolution, will be to reveal the nature of the intermediate states between the fully reduced and fully oxygenated forms, which could not otherwise be observed by crystallography.

STRATIGRAPHY

Fixing a Boundary

from a Correspondent

IT cannot be often that the Red Army is responsible for a geological article. In August 1968 the International Commission on Stratigraphy met in Prague and was about to consider a proposal that the boundary between the Silurian and the Devonian should be fixed at the base of the *Monograptus uniformis* Zone, which is appreciably below the traditional base of the Devonian in Russia and Czechoslovakia, but unfortunately well above its base in Britain. The practical consequence of this in the classic area of the Welsh Borderland would be to transfer the lowest Devonian strata as originally defined by Murchison to the Silurian system. The support for the proposal suggests that it would have been accepted had the work of the commission not been interrupted. Because of the invasion, however, the matter is still open to debate. Westoll, Shirley, Dinely and Ball have recently taken advantage of this respite to argue (*J. Geol. Soc.*, **127**, 286 ; 1971) that the traditional position of the boundary between the two systems should be retained.

This may seem a rather arid discussion of interest solely to specialists. In

Marine Bands and Tonsteins revealed in Derbyshire

THE Westphalian Coal Measures are remarkable for the continuity and persistence of certain rock types, especially the marine bands which have characteristic fossil fauna resulting from relatively short lived but widespread marine invasions of the coal delta. These bands have long been accepted as reliable stratigraphic markers on which to subdivide and to correlate the coal measures of the British Isles and Europe. The thin, curious, kaolinitic bands called tonsteins discovered more recently in the coalfields of Western Europe have provided welcome additional markers for correlation purposes.

Tonsteins were first found in North Staffordshire in 1961 and discoveries in other British coalfields have followed, particularly at one horizon below the equivalent of the *Edmondia* Marine Band. They are usually only a few centimetres thick, yet some of them are traceable over hundreds of square miles and, as in the case of some marine bands, a few can be traced throughout the coalfields of Western Europe. Their origin is problematical and probably varied; the volcanic ash idea is attractive in terms of widespread persistence but it is also held that they are the result of special soil forming processes.

In the forthcoming issue of *Nature Physical Science*, M. A. Calver, who has been associated with many discoveries of new marine bands in British coalfields, is joined by B. C. Worssam and G. Jago to demonstrate again that continuous core drilling coupled with examination can still reveal hitherto unproved marine bands and tonsteins. A series of boreholes drilled in the Pottery Clays of the South Derbyshire Coalfield during 1970 on behalf of the Institute of Geological Sciences and the National Coal Board have added considerably to the knowledge of the stratigraphy of these coal measures. Above the Overseal Marine Band Calver *et al.* have recorded the presence of the marine bands equivalent to the Top, Shafton and *Edmondia* Bands of the East Pennine Coalfields and they have also recorded a tonstein which occurs a little below the last of these bands at about the position of the Sub-High Main tonstein; another new tonstein is located between the Top and Shafton marine horizons. The elusive marine bands between the Overseal and underlying Two Foot have also been found and correlated.

fact, it arises from a more important philosophical question—how geological time should be measured. When stratigraphy was in its infancy, it was natural to fix on spectacular events the effects of which were readily apparent and to use these for dividing the geological record.

More recent ideas on the philosophy of stratigraphy, however, suggest that time is a continuum, and that stratigraphic boundaries are merely arbitrary divisions, much as the hours of the day are arbitrary. Once a boundary is agreed, and defined by a type section, stratigraphers can get on with their real business—correlation. From this it follows that type sections should be chosen in areas where the rocks have all the features useful in correlation—good varied faunas (preferably marine) and as few obvious breaks as possible. This means that the traditional type sections of the Silurian/Devonian boundary in the Welsh Borderland just will not do—not only are half the rocks continental, but the famous Ludlow Bone Bed represents a marked time break. A very suitable type area seems to be the Barrandium Syncline near Prague, which was protected from the major movements of the Earth which disturbed north-west Europe in early Devonian times and where the graptolites, all-important in correlation, were not forced to extinction.

Geologists are agreed that the new proposal presents British stratigraphers with some difficulties, as Westoll and his colleagues point out. They suggest that the boundary should be fixed at another graptolite zone rather lower in the succession, marked by *Monograptus ultimus*, which would give a boundary very close to the position of the Ludlow Bone Bed.

Not all their British colleagues take this view; there is considerable British support for the new proposal. It will be interesting to see whether Westoll, Shirley, Dinely and Ball are fighting a rearguard action or starting a successful counter attack.

OLFACTION

Smells Left and Right

from our Membrane Correspondent

IT has been reported that compounds, which differ only in their stereochemical configuration about one carbon atom, have distinguishably different odours. It is possible, however, that the difference in smell between these enantiomers can be attributed to that bugbear of olfactory research, the presence of unidentified impurities.

Earlier this year Leitereg *et al.* (*Nature*, **230**, 455; 1971) presented good evidence that the optical isomers (+)- and (−)-carvones, prepared from both natural and synthetic sources, have different odours—caraway and spearmint respectively—but these authors still paid lip service to the possibility that the odour difference was caused by impurities. This possibility has now been convincingly eliminated in some recent work reported by Russell and Hills (*Science*, **172**, 1043; 1971) and by Friedman and Miller (*ibid.*, 1044).

Russell and Hills investigated five different enantiomeric pairs of compounds—(+)- and (−)-carvones and four derivatives of each of these. The actual samples used for odour evaluation were purified fractions which were collected after successive passages through two different gas-liquid chromatography (GLC) columns. In each case there was a highly significant difference in odour quality. Using GLC and a variety of synthetic pathways, Friedman and Miller investigated eight different enantiomeric pairs which had distinct odour differences. All but one (amphetamine) of the pairs were terpenoid compounds and these included the carvones and also (+)- and (−)-limonenes; the last two had the odour of oranges and lemons respectively—as in the case of the carvones this is a far from subtle difference in odour. Friedman and Miller paid particular attention to the carvones; they resolved a racemic mixture, synthesized them by two different routes and also subjected them to a cycle of reactions which interconverted the + form to the − form and back again. The final products of all these manipulations were subjected to odour evaluation. The odours of the + forms were indistinguishable from each other as were the odours of the − forms, but the + and − pairs always had a significant difference in odour.

The postulated impurities now come to have unbelievable properties. There would have to be a different pair of impurities for many of the enantiomeric pairs studied, and in each case these impurities must survive both the GLC purification and the wide variety of chemical manipulations. Furthermore, just the same impurities would have to be present in both natural and synthetic compounds.

The vibrational and rotational modes of enantiomers are identical so that the now clearly established fact that enantiomers can have different odours spells death to any theory of olfaction which looks for correlations between odour quality and infrared spectra. Furthermore, other theories are now faced with the task of explaining why some enantiomeric pairs have different odours and other pairs have identical odours.

Some Pulsars May Emit Thermal X-rays

THE view that pulsars may consist of a superfluid core of neutrons surrounded by a rigid crust, as suggested by Baym, Pethick, Pines and Ruderman, is examined by George Greenstein of Princeton University Observatory in next Monday's *Nature Physical Science*. So far the attraction of the model of Baym and his colleagues has been that it accounts in a neat way for some of the irregularities in the behaviour of pulsars, interpreted in terms of starquakes occurring in the rigid crust. In this model the slowdown of the spin of the pulsar is accompanied by frictional heat as a result of slippage between the crust and the core.

Greenstein has evaluated the magnitude of this heating, which is on top of the temperature expected for pulsars on the basis of cooling theory, so that the temperatures which he obtains from an examination of the slowdown of pulsars can be considered as lower limits to pulsar temperatures.

It will not come as a surprise that the two pulsars for which the frictional heating process seems significant are the two fast pulsars, in the Crab Nebula and in Vela. For both these objects Greenstein finds temperatures caused by frictional heating arising between the rigid crust and neutron superfluid of 10^6 K. He suggests therefore that thermal X-ray emission ought to be detectable from these two objects—he expects them both to have X-ray fluxes of the order of 3×10^{-27} erg cm^{-2} s^{-1} Hz^{-1}.

It may also be possible to detect the thermal X-ray flux of 1×10^{-28} erg cm^{-2} s^{-1} Hz^{-1} that is expected from what is thought to be the closest pulsar, CP 0950. Another possibility is that pulsars the orientation of which is such that their pulsations are not detectable at the Earth may be discovered by their thermal X-radiation.

But for other pulsars the expected thermal X-ray emission is appreciably weaker—1×10^{-30} erg cm^{-2} s^{-1} Hz^{-1} for HP 1508 and 3×10^{-29} erg cm^{-2} s^{-1} Hz^{-1} for CP 1133. For these two objects the expected associated visual magnitudes are 32 and 27 respectively, far beyond the capabilities of the best optical telescopes.

Greenstein also reports that the heating at the inner boundary of the core takes place in a thin shell that can be a kilometre or so, or less, in thickness. He also points out that his equations indicate that fluctuations in the temperatures of pulsars are mirrored by corresponding fluctuations in the periodicity of the pulses, so that the regularity of pulsars implies that their temperatures are also kept amazingly constant.

NUTRITION

New Protein Foods

from a Correspondent

THE conference at the University of Reading, from July 13 to 15, on the topic of new protein foods differed from many others on the same subject in that it was confined to agricultural conditions in the United Kingdom. In his introduction, Professor F. Aylward (University of Reading) classified the different kinds of new protein foods and stated that a crop for the production of protein concentrates depends in practice on a combination of factors including (1) yield of protein, (2) technical problems of harvesting, extraction and processing, (3) nutritional value of protein and freedom from anti-nutrient or toxicological factors, (4) acceptability of product for direct use as a food or as a food component, and (5) economic and commercial considerations. The yield of protein depends on the percentage of protein in the crop, the total yield of crop, the actual yield of protein after harvesting, and the yield after processing.

Dr R. R. Robinson (University of Reading) described the use of bacteria, yeasts, fungi and chlorophyll-containing plants such as unicellular algae. There are many difficulties to be overcome regarding the extraction of protein from these organisms and oilseeds, legumes and cereals are likely to be the chief source of protein during the next two or three decades. Dr B. J. F. Hudson (University of Reading) ventured to predict the possible increase in consumption of these foods in the United Kingdom up to AD 2000. On the basis of careful calculations by forty different experts it seems that textured proteins and similar plant protein concentrates might replace as much as a quarter of the meat by AD 2000, or even earlier. Professor H. M. Sinclair (University of Oxford) dealt with the nutritional potential of these new protein foods. He emphasized the importance of ensuring a sufficient content of vitamin B_{12}, with fortification if necessary, and pointed out the valuable clinical work which is being carried out on vegans living only on plant foods.

Dr M. A. Crawford (Nuffield Institute of Comparative Medicine, London) emphasized the importance of other factors besides protein in the new foods and drew attention to the role of structural phospholipids in the brain and other parts of the central nervous system. Both Professor Sinclair and Dr Crawford said that the correlation between too high a level of total phospholipids and nervous diseases seems to be connected with the phospholipids breaking down, but they did not state the cause.

Meat production and demands in the United Kingdom were described by Mr H. F. Marks (Meat and Livestock Commission) and Dr A. M. Ashby (Unilever Ltd). Although Britain's entry into the Common Market would be expected to cause rises in meat prices probably greater than the corresponding income rises, they thought that the total consumption of meat would not fall much, although they agreed that much more consumption of these new protein foods will gradually develop. Dr W. F. Raymond (Grassland Research Institute, Hurley) suggested that the high cost of meat production might be curbed to some extent by using alternative feeding stuffs including perhaps those made from microorganisms.

Dr M. A. B. Boddington (Wye College, London) applied land use projections for the next 30 years to forecast possible developments in yields from land which might improve the present low conversion efficiency of only 6 per cent for beef and 12 per cent for pigs.

REVERSE TRANSCRIPTASE

Templates for Caution

from our Cell Biology Correspondent

As Speigelman in particular has of late taken great pains to emphasize, enzymatic activities detected by their ability to use synthetic RNAs and RNA/DNA hybrids as templates for the synthesis of DNA cannot be immediately equated with the reverse transcriptases found in animal tumour viruses. The enzyme or enzymes in such viruses—and there is still some dispute as to whether or not a single enzyme molecule can complete the synthesis of a double stranded DNA from the single stranded RNA viral genome (Robinson and Robinson, *Virology*, **44**, 457; 1971)—use endogenous viral RNAs, synthetic RNAs and hybrids as templates for the synthesis of DNA. But it does not inevitably follow that all enzymes which *in vitro* can be programmed by synthetic RNAs or hybrids to polymerize deoxynucleoside triphosphates function *in vivo* as authentic reverse transcriptases and have an endogenous and natural single stranded RNA template. Synthetic nucleic acids are useful templates for the detailed investigation of reverse transcriptases once the enzymes and their natural templates have been identified, but the identification of a reverse transcriptase in a new situation depends on the identification of its natural template.

Indeed if the ability of an enzyme to use synthetic RNA as a template for DNA synthesis *in vitro* is taken to be diagnostic of its function *in vivo* as a reverse transcriptase, the Kornberg DNA polymerase I of *Escherichia coli* must be classified as a reverse transcriptase. For as long ago as 1963–4 Cavalieri and his colleagues proved that DNA polymerase I can utilize double stranded synthetic RNAs as

Oncogenicity of Cleaved Adenovirus DNA

ALTHOUGH the adenoviruses apparently cause nothing more devastating than respiratory infections in their natural hosts, at least some of them induce tumours when they are injected into newborn rodents and will transform some of the cells which they infect *in vitro*. Attempts to analyse genetically the oncogenes in adenovirus genomes, by the isolation of temperature sensitive mutants, seem most promising, but meanwhile Mayne, Burnett and Butler have set about the physical isolation of fragments of the simian adenovirus 7 (SA7) genome which contain these genes. Next Wednesday's *Nature New Biology* contains their progress report.

Having first shown that intact DNA isolated from SA7 is not only infectious but capable of inducing tumours when injected into newborn hamsters, they have now fragmented this DNA, either by sonication or by shearing it through a syringe, fractionated the fragments and tested their oncogenic potential. Molecules roughly half the size of the complete genome, which can be separated by virtue of their density into heavy and light halves, induce tumours like intact molecules. By contrast smaller fragments obtained by sonication are not oncogenic.

The induction of tumours by both heavy and light "half" molecules, but not by smaller pieces, is of course disappointing to anybody bent on physically isolating the SA7 oncogenes free of any other genetic material. For although these experiments prove that the whole genome is not essential for oncogenicity the fact that both halves of the genome have oncogenic potential may well mean that several regions of the genetic material, rather than a unique segment, contain oncogenes. Alternatively and more optimistically, it might be argued that the oncogenes are centrally located in a small segment of the genome, which, depending on the precise point of cleavage, might be included in either the heavy or the light "halves". The hybridization studies between "half" molecules and DNA extracted from the cells of tumours induced by heavy and light "halves" that Mayne *et al.* promise may perhaps resolve this issue.

well as single stranded natural RNAs as templates for DNA synthesis. And, rubbing home the message, Cavalieri and Carroll reported two weeks ago in *Nature* (**232,** 254; 1971) that the addition of traces of calf thymus DNA to *E. coli* ribosomal RNA resulted in a three to ten-fold increase in the incorporation of the four deoxynucleoside triphosphates catalysed by *E. coli* DNA polymerase. This result is, of course, entirely reminiscent of the stimulatory effect of Goulian pieces on DNA synthesis catalysed by DNA polymerase I with natural DNA templates.

Mindful of these findings, it is perhaps rash of Werner *et al.* (*Biochem. Biophys. Res. Comm.*, **44,** 433; 1971), who have found that skin cells from people with xeroderma pigmentosum contain an enzymatic activity, which uses poly rG.dC as a template for DNA synthesis, that is absent from normal human skin cells, to conclude that xeroderma pigmentosum skin cells are infected with a tumour virus and contain a reverse transcriptase. In the light of Cavalieri's experiments and Spiegelman's cautionings one can offer an equally plausible alternative explanation of the data Werner *et al.* present.

There can be no questioning the fact that xeroderma pigmentosum cells lack some if not all DNA repair mechanisms and fail to excise pyrimidine dimers. Moreover this defect may well be responsible for the greatly enhanced incidence of skin carcinomas among people with xeroderma pigmentosum. Perhaps the different responses to poly rG.dC and native DNA of extracts of normal and xeroderma pigmentosum cells, which Werner *et al.* have detected, are the result of a mutation which has changed the template specificity of the cell's DNA repair enzyme(s). If human DNA repair enzymes resemble *E. coli* DNA polymerase I they will no doubt be induced to use, in the highly artificial environments set up by biochemists, synthetic RNAs and DNA/RNA hybrids as template. It does not take much stretching of the imagination to picture a mutation which would cause such an enzyme to use RNAs and hybrids in such experimental conditions in preference to native DNA, and at the same time impair DNA repair *in vivo*.

CONSERVATION

Rhinos Survive

from a South African Correspondent

DURING the early history of South Africa at least two big game species, the true quagga, *Equus quagga,* and the bluebuck, *Hippotragus leucophaeus,* were exterminated and many other species were severely curtailed in numbers and distribution. The approach to these matters has now improved considerably, however, as is shown by two recent reports.

One report by Dr U. de V. Pienaar, Nature Conservator of the Kruger National Park, points out (*Koedoe,* **13,** 157; 1970) that the southern white (or squarelipped) rhinoceros, *Ceratotherium simum,* is now safely re-established in the park after having been extinct in the eastern Transvaal for 65 years. The last white rhino in this area was apparently shot around 1896, when it seemed to be heading for extinction throughout its range. But it survived in the Umfolozi-Hluhluwe corridor complex in Zululand and gradually recovered so well that a danger arose of over-utilization and destruction of the available habitat. As long ago as 1928 the possibility of translocating rhino from Zululand to other parts of their former range was suggested by the naturalist Herbert Lang, but it was not until about 1960 that it became feasible for the Natal Parks Board to undertake large scale translocation. Even so, more than 1,200 animals remain in the Umfolozi-Hluhluwe corridor complex, so that the threat of over-utilization of the habitat has not been averted.

The second report, by Dr W. von Richter of the Mammal Research Unit, University of Pretoria (*Ann. Transv. Mus.*, **27,** 35; 1971), discusses the present status of the black wildebeest, *Connochaetes gnou.* This animal originally occurred extensively in the central open plains of South Africa, particularly the highveld grasslands of the southern Transvaal, Orange Free State and Karoo and the central and southern Cape grassveld. In addition it was probably a seasonal migrant into Natal. Within its range it was initially extremely abundant, but indiscriminate hunting, together with periodic disease outbreaks and gradual curtailment of the habitat to make way for human settlement, caused it to dwindle to about 600 animals, chiefly in the Orange Free State and southern Transvaal, by the turn of the century. Since then, however, numbers have increased steadily to more than 1,000 in 1945, about 1,800 in 1965 and 3,100 in 1970, as well as more than 155 animals living in zoological gardens in various parts of the world. The most marked increase has been in the Transvaal.

Von Richter concludes that, whereas it was thanks to the initiative of a few farmers that the black wildebeest was saved from extinction, an important factor in its survival has been the establishment of breeding herds in the national parks and provincial reserves.

Structure and Base Composition in DNA

IN the next issue of *Nature New Biology,* Bram contradicts the crystallographic dictum that DNA conformation is essentially independent of base composition. From X-ray scattering envelopes on gels or concentrated solutions, Bram previously found that the conformation of a DNA of typical base composition was little different from the B-structure found in fibres at high humidity. The same was true for DNA within calf thymus nucleohistone. A comparison of observed with calculated scattering curves indicated a small difference in the helix twist from that of B-DNA. Bram has now examined two bacterial DNA species containing 67 and 69 per cent of (A+T), as well as the alternating polymer, poly d(AT), and he reports that these do not fit the same model. The axial radius of gyration is similar, but the cross-section of the AT-rich species has much greater anisotropy. The curves fit neither a B nor an A nor a C-type of model, but all that can be said about the geometry of the new structure at the present stage is that the helix pitch is some 10 per cent larger than that of DNA of lower AT content. Bram suggests that the difference may be in the pucker of the sugar ring.

Bram notes that the transition of the DNA structure between the two forms is highly cooperative, in the sense that a large structural difference is observed between molecules containing 56 per cent and 67 per cent (A+T), but as between 56 per cent and 28 per cent (A+T) there is no further detectable change. Whether this apparent disagreement with earlier X-ray diffraction studies on fibres is a result of inadequate diffraction data on high-AT species, or on differences between the fibre and solution tates, remains to be established.

The biological implications of the findings that Bram reports may well be profound. If, as he suggests, AT-rich regions in a single chain cause alternation between the two types of structure, this offers a basis for a whole series of protein recognition processes. Some enzymes, repressors, and such molecules as polylysine, all show a strong binding preference for DNA species rich in (A+T). In bacterial DNAs tracts extremely rich in (A+T) have in fact been found. The observations would also make necessary a re-examination of the dependence of spectroscopic and other properties of DNA on the base-composition. The possibility exists that a similar effect may occur in RNA.

Value of Historical Records of Earthquakes

N. N. AMBRASEYS

Engineering Seismology Section, Imperial College, London SW7

Modern earthquake catalogues have been found unreliable in reporting earthquakes which occurred before 1900, because of a series of errors perpetuated at second and third hand. A new study of the original records provides significant data relating earthquake activity in the Eastern Mediterranean basin with plate tectonic activity over the past 2,000 years.

It is now recognized that any hope for earthquake prediction rests on increasing knowledge of earthquakes and their causes as well as of their effects. Almost all estimation of seismicity is probabilistic and the probabilities may be computed from observed occurrences of earthquakes. Yet the length of time covered by seismological data is negligibly short when compared with the geological time scale involved in the seismicity of a region. In a given sample period, small events are more numerous than large earthquakes, which are important but rare events, and are not easily counted unless the period of observation is large. Thus, in spite of the considerable volume of data for earthquakes in the present century, a much longer period of observation is needed to permit a meaningful statistical treatment. This can only be achieved by resorting to data for earthquakes before 1900 and by choosing for study seismic regions which have a long and well recorded history.

The region selected for study is shown in Fig. 1; it comprises the Eastern Mediterranean basin which has a very long and well documented history. Initially, the work was based on a number of earthquake catalogues and other modern works dealing with earthquakes before 1900. But after checking a number of suspect entries against the original authority quoted, I found that in general these catalogues were unreliable. Additional checking proved that entries were based on comparatively modern works and on early sources of information at third hand[1]. Apparently, seismologists who have often had to use literary sources at second hand have not been able to study early accounts critically. Thus, on many occasions, the same event, being described differently by various sources, was entered in their catalogues as two or even more events. Most of these catalogues have been copied by others without checking the mistakes, which are now being repeated in increasing numbers from publication to publication.

Thus, after experience of the difficulties caused by accepting the wrong data of modern writers, I decided to make a fresh collection of data based on contemporary evidence alone, with earthquake events set forth in an account of the local history and geography, starting with the first century AD, and avoiding the use of modern works.

Basic data were first drawn from the Teubner Series (3.5%)* as well as from the Patrologia Graeco-Latina (10.5%), and these were supplemented by information extracted from the Corpus Scriptorum Historiae Byzantinae (6.0%). Information from these sources provided a broad basis for the study of events before the sixteenth century. This information was augmented and cross-checked with data in the special publications of a considerable number of early writers (16.0%), bringing the period of observation up to AD 1700. At this stage, a number of problems arose in connexion with the dating of certain events, and also with the location of a considerable number of the sites mentioned in early documents. For the period between the sixth and fourteenth centuries, Syriac sources (2.5%) not only added new material but also resolved some of the chronological ambiguities. The use of contemporary Arabic sources (22.0%) also added a very substantial amount of fresh information, particularly for the period between the ninth and the seventeenth centuries, and helped disentangle some of the dating and siting problems; they did create, however, new difficulties in chronology, some of which were resolved using both Armenian and, to a lesser extent, Georgian sources (8.5%). The most invaluable sources of information were found in manuscripts (14.0%), particularly in the form of marginal notes and colophons. For the most part these are eye witness or contemporary accounts usually providing accurate dates or reliable information from which the actual dates could be derived; they describe events in remote areas, usually in monasteries far from large centres of culture, thus supplementing information from better known chronicles. For the whole period studied so far, inscriptions (1.0%) and a very small number of coins were found useful not only for dating events but also for assessing the degree and extent of damage caused by a particular earthquake; public assistance and private generosity are usually recorded. The issue of new coinage and the establishment of new mints were often measures taken by early authorities to relieve regions after destructive earthquakes. Archaeological evidence from recent excavations was also helpful, particularly in regions for which written evidence is either inconclusive or scarce.

Of the earthquake events identified in the course of the past ten years of the present work, most have been found in my own perusal of the original documents, which is still far from complete. The material available at present, however, is coherent enough to permit some conclusions to be drawn about the historical and scientific value of earthquake records for the first sixteen centuries AD.

The total number of all earthquakes, large and small, identified so far for the period AD 10 to 1699, is just over 3,000, or about twenty times the number of genuine earthquakes listed for the same period in modern catalogues.

---

* Percentage of the total number of original sources.

Because of serious gaps in recorded history of the Greek mainland, Macedonia and Albania, the homogeneity of the data for this area is relatively low. For the area east of the fortieth meridian, including the Red Sea, and for the period before the seventh century, the homogeneity of the data is even lower. For the rest of the region the sources of information are uniformly distributed in space and time and for the larger shocks, about 2,200 in all, the homogeneity of the material can be proved to be satisfactory for the whole period.

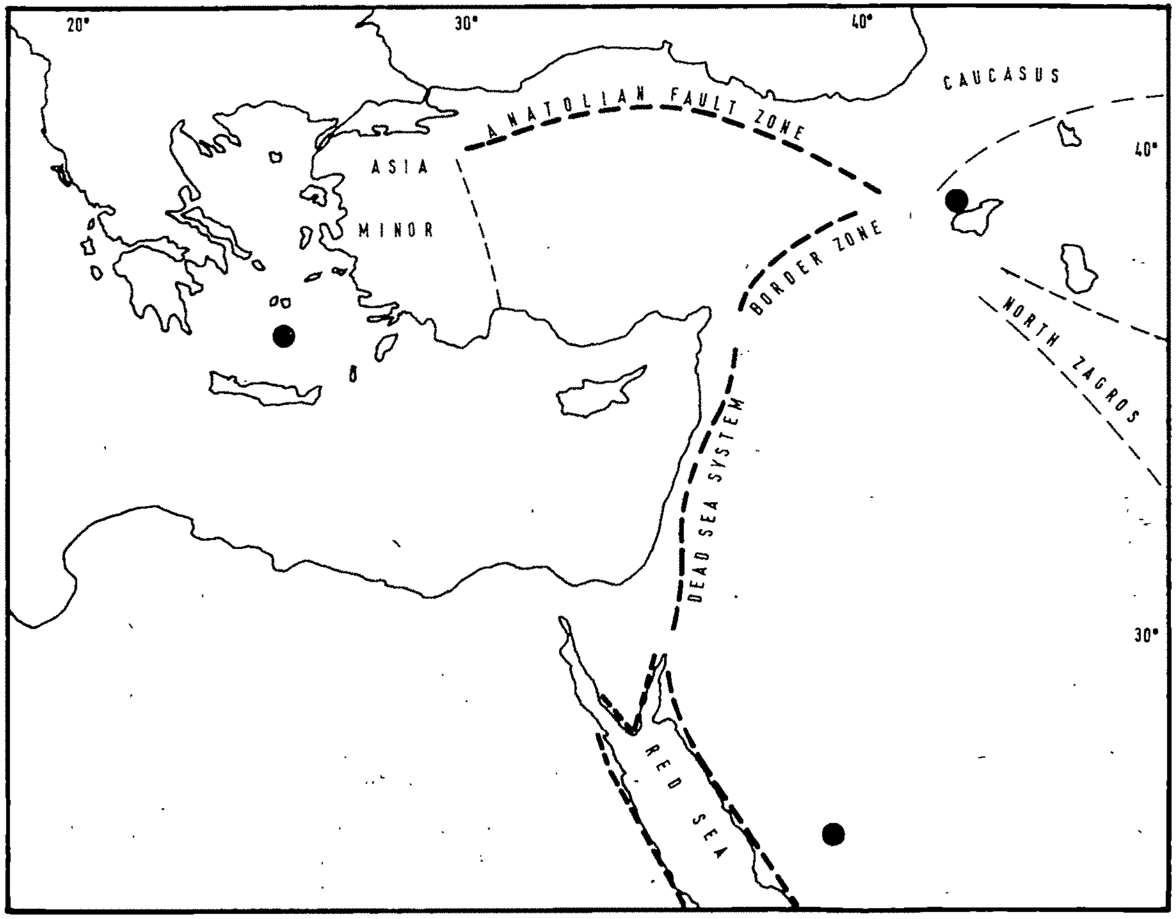


Fig. 1 The area of study.

It is often argued that it is the largest and most populous centres of culture that furnish most of the data about early earthquakes and that historical seismicity usually seems to be concentrated around large cities. This apparent concentration of seismicity is the result of the scanty and often inaccurate information given in modern earthquake catalogues. Modern writers seem to have been unable to study original sources critically or to identify localities affected by early earthquakes other than obvious ones. Thus, an unmodified use of the data in modern catalogues would lead to the absurd conclusion that the most seismic areas in the Middle and Near East are Istanbul, Antakya, Aleppo, and Jerusalem. But earthquakes felt in and reported from large cities originated in most cases from epicentral regions 50 to 400 km away where they caused heavy damage, accounts of which have been found either in less well known chronicles or in marginal notes, colophons and inscriptions written in remote areas which for centuries remained unaffected by significant population movements or by changes in the density of population.

The method used for the study of early events can best be illustrated by summarizing a typical example, that of the earthquake in AD 17 which affected the region recently damaged by a destructive earthquake on April 2, 1968. The earthquake of AD 17 destroyed twelve cities along the river Gediz, from the Aegean coast to Alashehir (Fig. 2). The earthquake happened at night and the destruction it caused was aggravated by conflagration. As a result of the earthquake certain parts of the Gediz valley were uplifted and others sank, the ground opened up in places and large landslides added to the damage. This earthquake is mentioned by Strabo (xii, 8; xiii, 3/4) who names only Magnesia and Sardis. Tacitus (ii, 47) gives more information about the twelve cities destroyed, which he names as Myrina, Aegae, Kyme, Temnus, Apollonis, Hyrkanis, Hierocaesarea, Mostene, Temnos, and Philadelphia. Pliny (n.h. ii, 200) and Seneca (n.q. vi, 1) call this earthquake a major disaster and give twelve as the number of the cities destroyed. Dio (1 vii, 17) attests the dispatch to Asia Minor of a senatorial commissioner with five lictors charged with the relief of the area as well as the remittance of large sums of money for reconstruction. Eusebius (2032) places this event in a.A. 2032, commencing October AD 16 and also in the third year of Tiberius, which are consistent with AD 17, but adds to the destroyed cities Dia and Ephesus. Hieronymus (566) adds Ephesus and Dia, but dates the event in the fifth year of Tiberius which is at least one year too high. *Chronicon Pseudo-Dionys* 93 gives the same date but adds only Ephesus. Later writers follow either Eusebius or Hieronymus, and some of them omit Kyme. Most of the earlier sources, Prosper (372), Dion. Telmar (46), Syncelus (319/603), record this earthquake in a.A. 2032, ending in October AD 17. Eusebius as well as Hieronymus add to the list a fourteenth city, Dia, which they do not count, however, and which is not mentioned in the Puteoli inscription. This inscription was found at Puteoli and bears the names of the twelve cities destroyed by the earthquake as well as that of Ephesus (CIL x, 1624). As this monument was set up in AD 30, twelve years after the earthquake, it is almost certain that Ephesus may have suffered and been relieved at a later date than the rest. In AD 22 a monument was erected in Rome by the restored cities in gratitude to Tiberius (BMC. Emp. i, Tib, 70); this monument is also described by Phlegon (42) and it refers to the twelve cities excluding Ephesus. It seems very likely that Dia has been derived from the dative case of Apollonis through an oversight of a later copyist of Eusebius's work (dat. Apollonidia = Apollonia-Dia). As Dia is found in texts always following the word Apollonis, or as in the Puteoli inscription the two names are joined together giving Apollonidea, we may assume that Dia did not suffer from the AD 17 earthquake. It must be pointed out, however, that Dia is given as a separate city damaged by this earthquake in Stephanus of Byzantium, who places it in Caria; perhaps Stephanus confused Dios Hieron, which is situated a few kilometres north of Ephesus in Lydia, with the alleged city of Dia. Sardis and Magnesia were almost totally destroyed

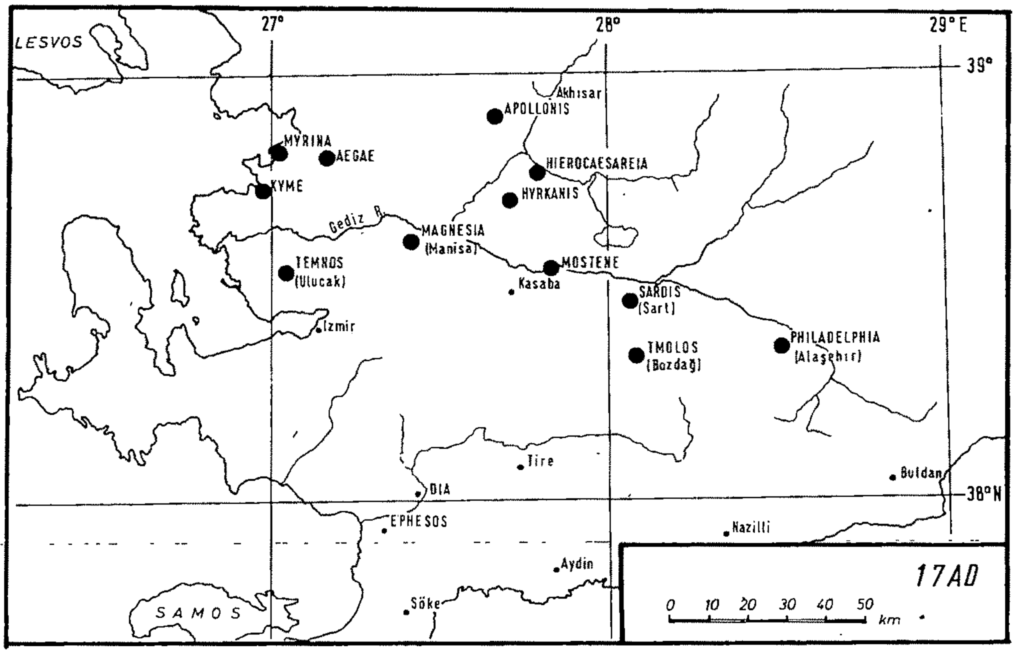

Fig. 2 Area affected by the earthquake of AD 17.

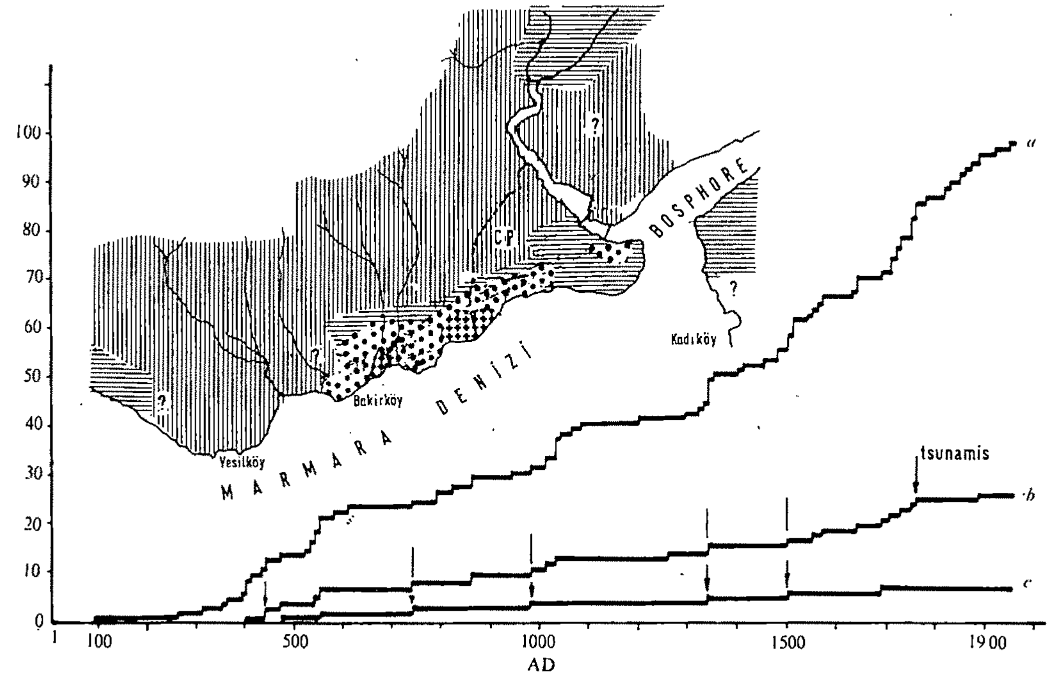

Fig. 3 Seismic activity in the Istanbul region.

and received considerable financial assistance from Rome as well as remission of all contributions to the Imperial Exchequer for a period of five years. Remission of tribute to the public exchequer for the same period was given to the other ten cities, *Res Gestae divi Augusti*. Sardis was rebuilt on an extensive plan. Recent excavations show an unusual type of foundation construction used in the reconstruction of the part of the city on the east bank of the Paktolos river—a grid of wooden beams under the foundation on which the structure was built. All evidence shows that this was a major earthquake.

From the study of individual events, in a manner similar to that given above, the seismicity of a particular area may be investigated over a long period of time. A typical though not the best example of early seismicity is that for the region of Istanbul. Fig. 3 (curve *a*) shows the time distribution of all strong earthquakes that caused alarm and also some damage in the city. There are two conspicuous periods of relative quiescence, and about 200 years long, centring on the seventh and twelfth centuries respectively. These are periods of genuine inactivity and are not due to lack of information. Indeed, the second of these periods coincides with the period of the Crusades for which we have the largest amount of information from occidental sources. From the same figure we notice that the frequency of occurrence of strong earthquakes in the fifth and sixth centuries is the same as that for the period after the fifteenth century. Fig. 3 (curve *b*) shows a similar plot for shocks that caused widespread concern over a large area and also considerable damage in Istanbul. Long periods of quiescence are again noticeable, but also groups of strong earthquakes, marking distinct increases in seismicity, with an average rate of about one damaging earthquake every 55 years. Finally, Fig. 3 (curve *c*) shows the distribution of destructive earthquakes that ruined large parts of the country around Istanbul, causing heavy damage with large numbers of casualties in the city itself. Some of these shocks were followed by comparatively short periods of high seismicity which often occurred near the end of long periods of relative quiescence; most of these large shocks were associated with seismic sea-waves, some of which were of catastrophic magnitude.

Frequency curves, similar to those shown in Fig. 3, have been prepared and studied for a number of regions. They show that earthquake frequency is subject to marked fluctuations rather than to any general monotonic variation. They show also that the data available for the seventeen centuries are sufficient for the detection of secular changes in local seismicity but inadequate to establish whether these changes are subject to a law. It is my impression that historical data are useful for the study of continental tectonics, of the migration of seismic activity in contiguous tectonic units as well as of the interaction between such units. For prediction purposes, however, a much longer period of observations is needed, for which no foreseeable means of data gathering seems likely.

The distribution of historical seismicity is shown by the shaded areas in Fig. 4. This map was constructed by superimposing all epicentral areas of individual earthquakes such as the one shown in Fig. 2. The map shows quite clearly that

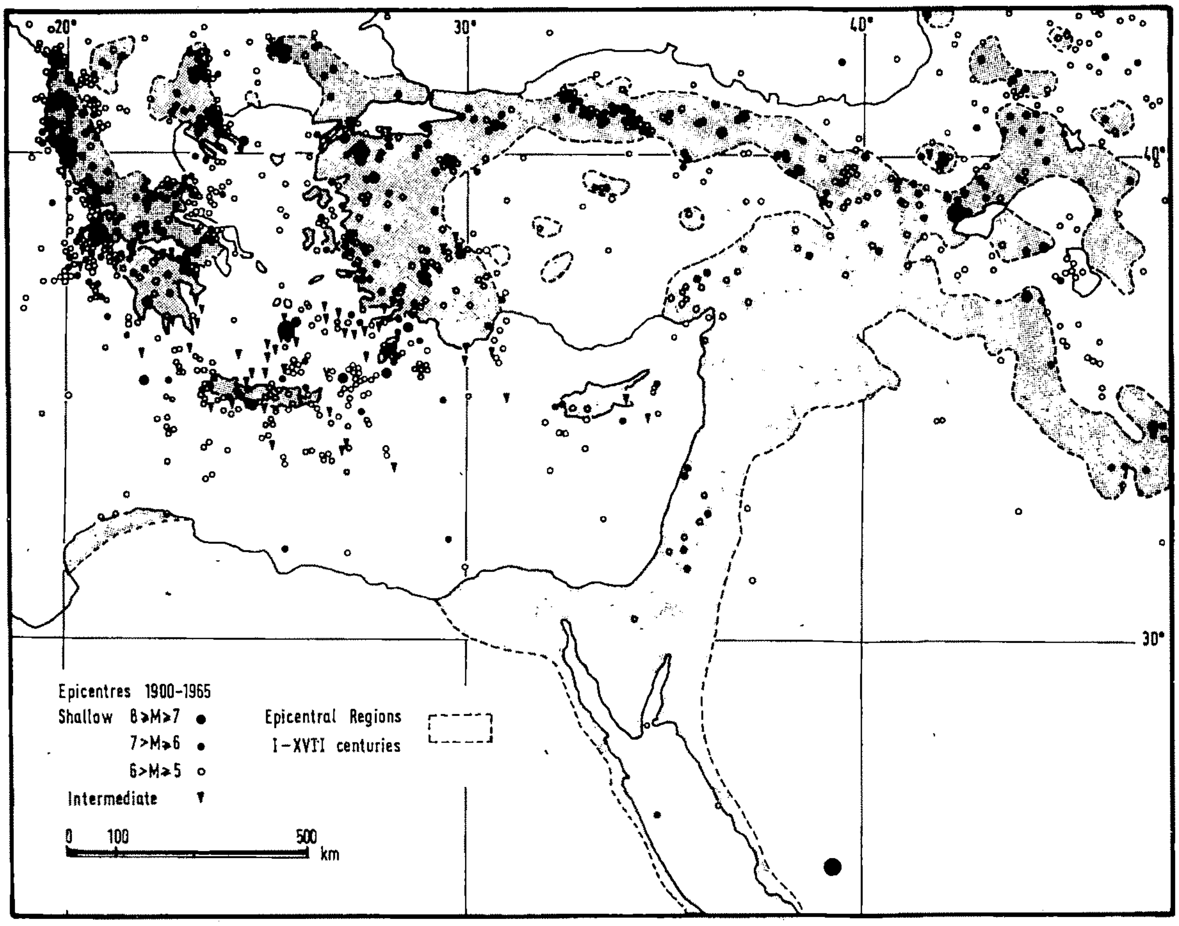

Fig. 4 Distribution of historical seismicity.

historical seismicity follows not only a well defined pattern but also that this pattern fits surprisingly well to boundaries of major tectonic units (Fig. 1). Thus the Red and the Dead Sea Systems, the broad Border Zone and its contact with the Anatolian Fault Zone and North Zagros, are very well defined. Complex zones in Greece and in western Asia Minor are less clearly depicted.

Instrumental data for the past 65 years, shown on the same figure, fit the pattern of early seismicity equally well. There is, however, a noticeable lack of instrumental data in the Border Zone, in the Zagros and in the Red and Dead Sea systems, which is obviously due to the relative quiescence of these regions during the present century. Consequently, it would seem that in certain cases of continental tectonics the formulation of theories on the basis of instrumental data alone, without due consideration of the time-scale involved in certain seismic processes, is bound to lead to erroneous or incomplete results.

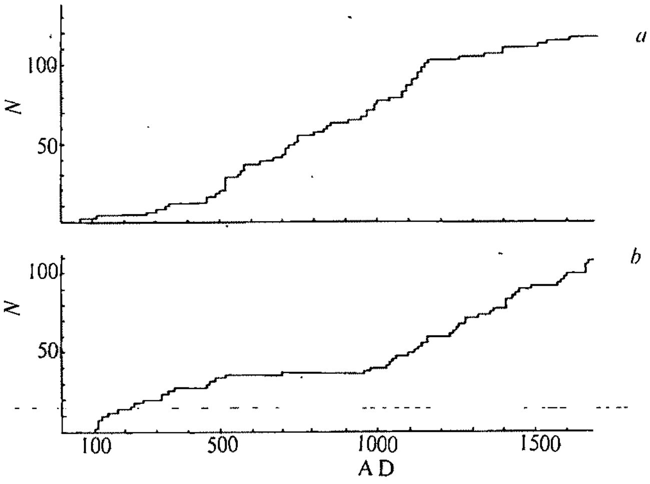

Fig. 5 Time distribution of damaging earthquakes. *a*, Border Zone; *b*, Anatolian Zone. N, Number of damaging earthquakes.

The study of interaction and migration of seismic activity in contiguous tectonic units is interesting. Fig. 5 shows the time distribution of damaging earthquakes (*a*) in the border zone and (*b*) in the Anatolian Fault Zone, the two units being contiguous. From this figure it is clear that during the first five centuries the Border Zone was comparatively quiescent while the Anatolian Zone was active. During the following six centuries the pattern was reversed, only to be reversed again during the eleventh century with a few centuries of overlapping activity. A similar cyclic pattern, but with longer periods of overlapping activity, was noticed for the Border Zone and the Dead Sea System. At this stage, however, a more detailed study of the interaction and correlation of activity of contiguous units is not warranted.

Faced with a high degree of uncertainty, but pressed by the requirements of a technical society for judgment and decisions, seismologists, geologists and engineers make daily estimates of seismicity with varying degrees of success. The study of historical earthquakes brings out two important points that should be taken into consideration when early events are used in seismicity assessments.

The first point concerns the interpretation of early earthquakes. To each of the curves shown in Fig. 3, or to any other frequency curve, corresponds a particular intensity, the precise value of which cannot be assessed. The reason for this is that intensity, being a measure of the effect of a particular earthquake on man-made structures, cannot properly be used to relate early and modern events. Modern buildings differ in many respects from old ones and to judge future damage from century old case histories can be seriously misleading. For instance, the exact repetition of an old earthquake at the present day will differ not only in the types of structures damaged but also in the degree of damage. In some cases modern structures will be more severely damaged than old buildings. A distant large earthquake ten centuries ago would have caused practically no damage in Istanbul, Ankara or Jerusalem; the same earthquake today would cause damage to a large number of long-period structures in these cities.

The second point concerns the assessment of seismicity using extant structures of old age. It is usually considered rather improbable that early structures, liable to damage by earthquakes, could stand for many centuries in seismic regions. The mere fact that quite a few early monuments are still to be found in a state of tolerable preservation in various parts of the world has led to the belief that these parts should be free from destructive earthquakes[2]. But historical and archaeological evidence shows that this is not the case. The early buildings that are still standing have in fact, during their lifetime, been subjected to a number of destructive earthquakes, and they have survived through a process of natural selection. They are a very small fraction of the total number of structures that existed in early times and they represent a sample of structures of the best final design and construction, achieved through the ages by a trial-and-error technique or by chance. Furthermore, frequent references occur in early literature to extensive repairs of walls, churches and other buildings, because of earthquake damage, where the occasion was taken to introduce changes in the design and construction which produced a more resistant structure. Thus, the mere fact that a few early monuments are still standing in various sites in Greece, Turkey, Iran or even in Skopje and in Istanbul, should not be taken to mean that these sites have been free from damaging earthquakes.

Perhaps it is one of our most interesting findings that the lasting effects of major earthquakes during the past twenty-five centuries would not seem to have been very significant. Soon after a large earthquake, vested interests invariably led people to act once again with disregard for the prospect of further such calamities. Yet modern writers[3,4] have attempted to use earthquakes to account for gaps in the sequence of civilizations and for movements of peoples, hypotheses for which I can find absolutely no historical justification. Earthquakes in the past twenty-five centuries have had little, if any, serious influence on historical developments in the Middle and Near East. They did often account for the premature decline of a local economy or for a crisis in local human affairs. But they have never caused the ruin of a culturally advanced state, far less the end of a civilization. In contrast with wars, epidemics and other long lasting calamities which have serious and prolonged effects, earthquakes, no matter how large, seem to have had little long-term impact on Man. It may be that men react to the inevitable hazard in a special way, distinct from the preventable hazards[5]. Personal, political and economic interests seem to overshadow, and in some cases suppress, the lessons to be learnt from destructive earthquakes. For example, villages ruined by early earthquakes are often rebuilt on different sites, whereas cities, where significant economic and political interests were involved, have been rebuilt, enlarged and embellished; invariably on the same site, even when it was known that the site was unsuitable and that it had contributed to the magnitude of the disaster.

This work, which began early in 1960 and which is still in progress, has been supported by UNESCO (1969–71).

Discovery of Postcranial Remains of *Homo erectus* and Associated Artefacts in Bed IV at Olduvai Gorge, Tanzania

M. D. LEAKEY

Centre for Prehistory and Palaeontology, PO Box 30239, Nairobi

The discovery of a left femur shaft and hip bone of *Homo erectus* in association with an Acheulean industry in Bed IV represents the first direct association at Olduvai of a well defined artefact assemblage with *H. erectus*.

THE shaft of a left femur and a pelvic fragment attributed to *Homo erectus* (Olduvai Hominid 28) that are described by Dr M. H. Day in the following article[1] were found *in situ* during excavations in 1970 at site WK (Wayland's Korongo), Olduvai Gorge. This site lies on the south side of the gorge, 1.25 miles below the junction of the main and side gorges. Hand axes and cleavers had first been observed there on the scree below Bed IV during 1932, but no excavations were undertaken before 1970, when a systematic exploration of Bed IV was carried out.

The two hominid bones were found on a well defined surface and lay 1.5 m apart, with the anterior aspect of the femur shaft and the interior or pelvic aspect of the innominate bone upwards. Several artefacts and broken remains of fauna lay nearby (Fig. 1). Subsequent excavations, during which approximately 18 × 10 m were cleared down to the level of the hominid bones, revealed that they were on the higher part of an uneven, eroded surface which could be traced over the whole of the exposed area. To the south-west, the surface dipped down into

a channel approximately 1 m deep that was aligned roughly NE–SW. Several irregular depressions were uncovered in the eastern part of the area, none of which exceeded 0.75 m in depth; the bases of these depressions and of small hollows in the principal channel were clearly marked by a thin coating of silt.

Both the principal channel and the depressions contained dense accumulations of occupational debris, incorporated in a coarse sandy matrix. This level yielded a total of 2,600 specimens comprising hand axes, cleavers and other artefacts, including artificially pitted stones, faunal remains and unmodified cobbles. Abrasion is evident on some of the specimens but many are sharp and do not seem to have been weathered or transported by water for any considerable distance.

Two more horizons containing artefacts were uncovered at this site, the lowest in a conglomerate at the junction of Beds III–IV and the second approximately 1 m below the hominid level (Fig. 2).

Geology of the Site

Dr R. L. Hay of the Department of Geology, University of California, Berkeley, whose monograph on the geology of Olduvai Gorge is now in preparation, has supplied the following note on the geology of the site, with the accompanying section (Fig. 3).

Bed IV ranges from 20–22 feet thick in the vicinity of WK. It sharply overlies Bed III and is overlain by aeolian tuffs of the Mesak Beds (formerly known as Bed IVb). Bed IV is 50%–60% claystone and most of the remainder is sandstone and conglomerate, which form lenticular beds. The claystones are usually sandy, root-marked, and locally contain vertical veins of sandy claystone a centimetre thick and a few feet long that represent deep mud cracks filled by sediments during the deposition of Bed IV. Most sandstones contain both volcanic and quartzose basement debris.

A marker tuff (Tuff IVB) extends through most of this area near the middle of Bed IV. It is as much as 7 feet thick, hard and reddish-brown, and is characterized by altered mafic glass and abundant rock fragments. Most of the tuff is thin-bedded or laminated. The tuff is locally eroded away and fragments of it occur in the lowermost sandstones and conglomerates above the tuff. The hominid fossils were found at the base of a sandstone with fragments of the tuff, showing that they postdate the tuff, but probably by only a short period of time.

Black denotes red beds

Fig. 3 Stratigraphic section of site WK prepared by R. L. Hay. Black denotes red beds.

The non-tuffaceous deposits of Bed IV are fluvial; sandstones and conglomerates fill the stream channels, and the claystones represent overbank deposits. The WK area lay near the drainage axis of the Bed IV basin which received volcanic detritus from the south and east, and basement detritus from the north and west. Tuff IVB was deposited in a temporary, small, saline playa lake, at a time when the climate was relatively hot and dry.

Recent geomagnetic polarity measurements on red beds provide a basis for tentatively estimating the age of Bed IV. A. Brock (University of Nairobi) has found reversed polarity in three samples from the upper part of Bed II and one from upper Bed III; a sample from near the base of Bed IV is normal. These few data, added to data from Bed I and the lower part of Bed II[2], suggest that the boundary between the Matuyama Reversed and Brunhes Normal epochs, dated at about 0.7 m.y.[2], lies approximately at the base of Bed IV. The Lemuta (= aeolian tuff) Member of lower Bed II has an age of about 1.65 m.y.[3]. Extrapolating on the basis of stratal thickness between the

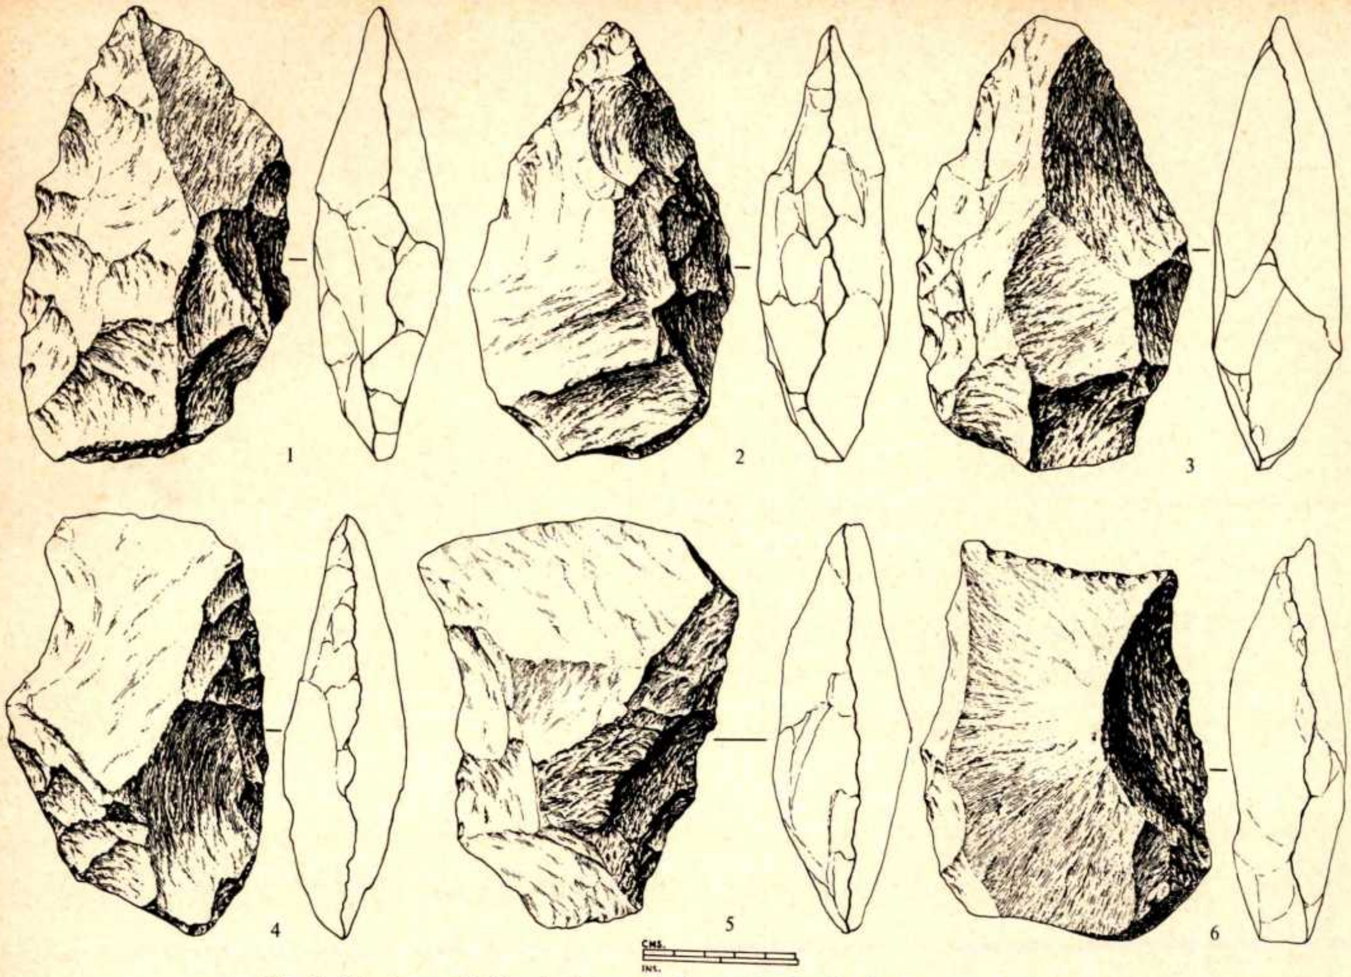

Fig. 4 Hand axes (1–3) and cleavers (4–6) associated with the *H. erectus* remains.

levels of 1.65 and 0.7 m.y., the top of Bed IV may be about 0.3 or 0.4 m.y. old, and the hominid fossils may have an age of about 0.5 m.y.

Artefacts

The sample of occupational debris reviewed here consists of 494 artefacts (Table 1), 347 unmodified cobbles and 257 largely fragmented remains of fauna. This material was obtained from one trench within the principal channel and can be considered to represent a fair sample from the hominid level.

Table 1 Artefacts recovered from Site WK

Tools	Nos.	%
Hand axes	20	15.9
Cleavers	23	18.2
Bifacial tools, broken and unfinished	7	5.5
Choppers	11	8.7
Discoids	9	7.1
Spheroids	10	8.0
Scrapers, heavy and light duty	24	19.0
Small tools, various	22	17.5
Utilized material		
Pitted cobbles	41	35.6
Cobbles, battered	20	17.4
Miscellaneous	50	43.5
Hammerstones	4	3.5
Debitage	253	

Most of the hand axes and cleavers have been made on side or end struck flakes, the former predominating. They are mostly of trachyandesite, though there are a few examples of phonolite and tabular quartzite. The striking platforms have been only roughly trimmed off and one face usually consists almost entirely of the untrimmed primary flake surface. With few exceptions these tools show a minimum degree of retouch and most of the trimming scars are large and deep. Only two specimens, both made from fine grained phonolite, exhibit some "resolved" flaking. The average number of trimming scars is low: 10.5 per specimen in both hand axes and cleavers, a figure that compares closely with that for the Early Acheulean hand axes from Middle Bed II[4]. The hand axes are roughly ovate in form but are markedly irregular. In the cleavers, square or oblique ended examples predominate and chisel ended specimens are rare. In spite of their general crude appearance, both hand axes and cleavers are more or less the same size and have similar breadth/length and thickness/length ratios; it is clear that they represent a homogeneous series (Table 2).

The forty-one pitted cobbles are a prominent feature of this industry and they also occur at other sites nearby of approximately the same stratigraphic level. These stones range in size from specimens no more than 5 cm in diameter to small boulders weighing several kilograms. The pits or hollows are also variable in size and measure from 1 to 5 cm in diameter. They sometimes occur singly, but are more often in pairs, one on either side of a stone; some examples have up to six hollows.

Table 2 Average Measurements of Hand Axes and Cleavers

	Length (mm)	Breadth (mm)	Thickness (mm)	Breadth/ length ratio (%)	Thickness/ length ratio (%)
Hand axes	142	84	41	61.3	28.9
Cleavers	133	90	45	67.5	34.2

Among the unspecified small tools are a number of thick-set quartz points, triangular or quadrilateral in cross-section, that are usually heavily utilized at the tips. These tools also occur at other sites where there are pitted cobbles and it seems possible that they were used in conjunction with the cobbles, perhaps as punches.

Artefact assemblages from three sites excavated within 1–2 km of WK, that are virtually contemporaneous with the hominid level, have still to be studied in detail, but it is clear that they are at variance with the WK industry in a number of important respects, particularly in the proportionately small numbers of hand axes, total absence of cleavers and relative abundance and variety of small tools. Large side and end struck flakes do not occur and the rare hand axes are made on small "cores" flaked over both faces. It is evident that the technique of biface manufacture was fundamentally different, although the materials used are the same and are also known to have been obtained from the same sources.

To conclude, the industry from the hominid level can be referred to the Acheulean in view of the proportionately high number of bifacial tools (39.6%), among which cleavers are unusually common. The hand axes bear strong resemblances to the Early Acheulean series from EF–HR in Middle Bed II, to which they seem closer than to contemporary series excavated from Bed IV.

Although other human remains that may be attributed provisionally to *Homo erectus* have been found at Olduvai, in upper Bed II[5] and in Beds III–IV[6], where abundant artefacts also occur, the discoveries at WK are the first occasion on which a well represented lithic industry has been directly associated. It is not certain whether this association implies that *H. erectus* was responsible for the industry, but it seems likely, because there are other lines of evidence at Olduvai suggesting a link between the Early Acheulean of Bed II and *Homo erectus*[4].

Postcranial Remains of *Homo erectus* from Bed IV, Olduvai Gorge, Tanzania

M. H. DAY

Department of Anatomy, Middlesex Hospital Medical School, London W1P 6DB

Anatomically, the postcranial remains of Olduvai Hominid 28 seem to have a close resemblance to the *Homo erectus* material from Choukoutien.

THE discovery of postcranial fragments of Olduvai Hominid 28 reported by Mrs Mary Leakey in the previous article[1] is of great interest because the bones throw some light on the structure and function of the lower limb skeleton of Middle Pleistocene hominines in East Africa. The only lower limb material of a hominine of this approximate age known previously consists of the femora from Choukoutien, China, and the femora claimed to be of this age from Trinil, Java.

The first Trinil femur (Femur I) was recovered by Dubois[2] and his workers allegedly from the same horizon as the calotte of "*Pithecanthropus*" *erectus* (Dubois, 1894)≡*Homo erectus erectus* (Campbell, 1964). At the turn of the century, the association of this femur with the calotte was strongly questioned, and often subsequently, on the grounds that its modern features are at variance with the more primitive features of the calotte. When Weidenreich later described[3] the Choukoutien remains of "*Sinanthropus pekinensis*" (Black, 1927)≡ *Homo erectus pekinensis* (Campbell, 1964), he would not accept that the Trinil femur should have been attributed to "*Pithecanthropus*" and stated that it ". . . must be attributed to a type more closely related to modern man" because it differed so markedly from the Choukoutien femora. Nevertheless, it has been widely assumed for 30 yr that the Trinil femur was good evidence that the lower limb of *Homo erectus*, and by inference the remainder of the postcranial skeleton, was fully evolved and virtually of *sapiens* type by the Middle Pleistocene in Java; it was thus assumed that the subsequent evolution of *Homo* was confined almost entirely to the cranium, jaws, teeth and brain.

The discovery of new femoral and pelvic material in East Africa, in a well documented layer associated with artefacts, casts serious doubts on this assumption.

The Femur

The femur is represented by most of the shaft; it lacks the head and the greater trochanter. Parts of the neck and the lesser trochanter are preserved but the shaft is broken off just above the popliteal surface (Figs. 1 and 2).

The shaft is flattened throughout its length with acute medial and lateral borders. The flattening (platymeria) of the upper end is exaggerated by the presence of a marked lateral expansion at the level of the gluteal tuberosity. The lower end of the shaft is just beginning to expand for the condyles at the point of breakage, and the upper end shows the beginning of the lateral expansion for the neck and the postero-medial expansion for the base of the lesser trochanter.

The medial border of the shaft is convex along its length and the narrowest point on the shaft (medial to lateral) is very near to the distal end. Laterally, the shaft is gently convex antero-posteriorly and gradually expands from the subtrochanteric region to the point of shaft breakage below. From the front the shaft is straight.

The muscular impressions on the bone are remarkably clear, particularly the direct attachment of the gluteus maximus which is a combination of a crista hypotrochanterica and a fossa hypotrochanterica. The third trochanter is not preserved, if it was present, but it is possible that there was a

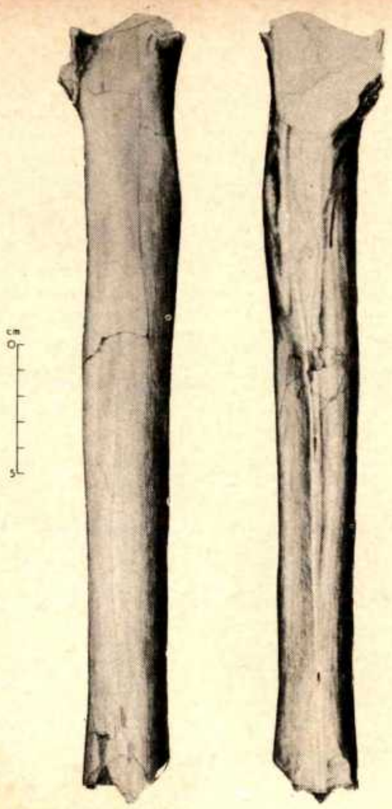

Fig. 1 Femoral shaft of Olduvai Hominid 28, anterior and posterior views. (Drawn by Audrey Besterman.)

tubercle at the top of the hypotrochanteric crest, a feature that continues up to the base of the greater trochanter.

At the upper end of the bone the spiral line is present for the attachment of vastus medialis muscle as well as a weaker pectineal line for the attachment of pectineus muscle; these lines are separated by a roughened area for the anchorage of iliacus muscle. Between the spiral line and the gluteal crest the upward extension of the ridge for adductor magnus can be discerned.

The ligaments around the hip joint seem to have been powerful because the sharp corner at the upper medial extremity of the specimen is crossed by the intertrochanteric roughening for the iliofemoral ligament; similarly, the triangular attachment of the medial band of the pubofemoral ligament is easily identified.

The linea aspera is present and divides towards the lower end into diverging medial and lateral condylar lines; there is no pilaster. Above, the attachment of vastus lateralis curves away from the linea aspera towards the lateral side and skirts the gluteal tuberosity; this permits the upper fibres of the short head of biceps femoris to mark the bone as a short ridge between the linea aspera and the gluteal tuberosity. There are three nutrient foramina, all small and placed near to the linea aspera.

X-rays show a thinning of the cortex towards the lower end of the specimen and the medial and lateral trabecular systems of the neck and upper end are clearly apparent. It would be impossible to see Ward's triangle, even if it were present, because it would have been above the upper fracture line. The medullary cavity is of moderate calibre and is generally wider than deep; the cortical thickness is greater in the coronal plane than it is in the sagittal plane at the mid-shaft. The range of modern human variability of total medio-lateral cortical thickness at the mid-shaft is large[4]. Hominid 28 shows a total thickness of 16 mm medio-laterally and 11 mm antero-posteriorly at the same point. The inferior aspect of the neck shows a well marked cortical buttress that is still 8 mm thick at the point of breakage; this is considerably thicker than is common in modern man.

The Hip Bone

The hip bone (os coxa) is represented by the major parts of its iliac and ischial portions (Figs. 3 and 4); the pubic portion is missing. The ischium lacks the tip of its spine and the ischial portion of the ischiopubic ramus, and the ilium lacks the anterior superior iliac spine. The specimen shows several cracks most of which are not displaced, but over an area of the anterior part of the iliac fossa there is a little distortion, so that there is an irregular depression of the surface and some lateral displacement of the anterior one-third of the iliac flange. This displacement is confirmed by the presence of an open crack on the medial aspect of the upper part of the anterior inferior iliac spine. Viewed from in front the ilium is canted laterally, slightly accentuating the prominence of the iliac pillar. The posterior half of the dorsum ilii also displays some cortical cracking with minor displacements and depression of the surface of the bone. There are several tooth marks on the specimen. There is no evidence of bone pathology or of the generalized effects of systemic disease.

The bone is stoutly constructed with prominent muscular and ligamentous markings and a large acetabulum indicating a large femoral head. The articular surface of the acetabular fossa is smooth and the non-articular region is thin. The ischium is relatively small by comparison with the acetabulum and is separated from it by a deep and narrow groove. This groove seems to be accentuated by the medially rotated position

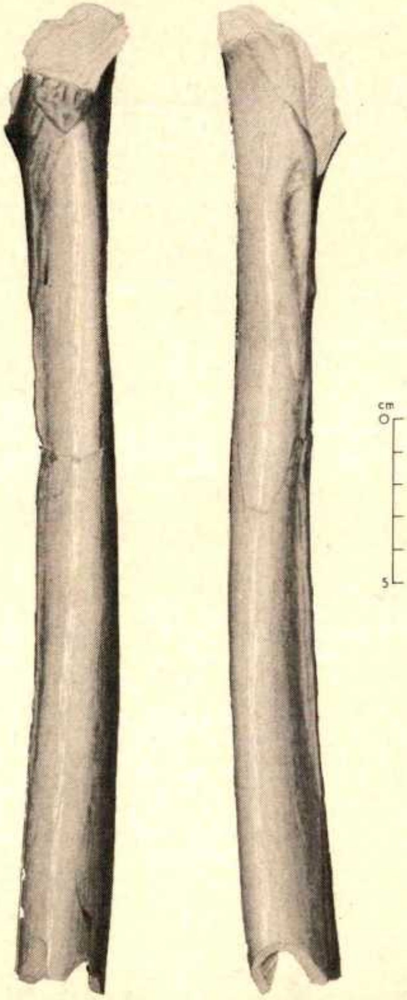

Fig. 2 Femoral shaft of Olduvai Hominid 28, lateral and medial views. (Drawn by Audrey Besterman.)

of the ischium. This also gives an appearance of shortness of the ischium that may not be fully borne out in reconstruction of the missing portion. The ischial tuberosity shows a well marked attachment for semimembranosus separated from that of the long head of biceps femoris and semitendinosus by the oblique ridge. On the lateral aspect of the ischial tuberosity the impression for quadratus femoris muscle can be seen, as well as some roughening for obturator externus muscle on the antero-lateral part of the ischial ramus. The medial surface of the ischium below the spine is smooth and rounded for the play of the tendon of obturator internus muscle.

The ilium is large and characterized by its prominent muscular markings and ligamentous impressions as well as the presence of an extremely robust vertical iliac pillar. Although it is true that this pillar may be slightly exaggerated by the distortion of the anterior part of the bone, none the less the feature is more prominent than on any modern human ilium so far examined. Correspondingly, the horizontal iliac bar which runs posteriorly from the acetabulum above the greater sciatic notch to the posterior iliac spine is very stout and well buttressed. Within the right angle enclosed by the vertical iliac pillar and the horizontal iliac bar the iliac fossa is very thin; the blade of the ilium has the characteristic hominid S-shape and it is set at a wide angle to the plane of the acetabulum.

The anterior superior iliac spine is missing but it may have been raked forward as suggested by the line of the anterior border as it runs upward from the anterior inferior iliac spine. The anterior inferior iliac spine is distinct and rounded showing a clear marking for the upper attachment of the iliofemoral ligament of the hip joint and another for the straight head of rectus femoris. To the lateral side of the spine the attachment of the reflected head of this muscle can be clearly traced above the acetabulum. Otherwise the gluteal aspect of the bone discloses a posterior gluteal line separating the attachments of gluteus maximus and gluteus medius as well as a middle gluteal line separating the attachments of gluteus medius and minimus. The pelvic aspect of the ilium shows a wide and shallow groove anteriorly for the iliacus muscle medial to the anterior inferior iliac spine; just below and behind the groove the iliopectineal line can be detected. In modern man this line is usually extended posteriorly as a ridge that separates the iliac fossa from the true pelvic wall, but in Olduvai Hominid 28 this ridge is missing; the iliac fossa runs smoothly down towards the greater sciatic notch and there is no excavation of the fossa above the horizontal iliac bar.

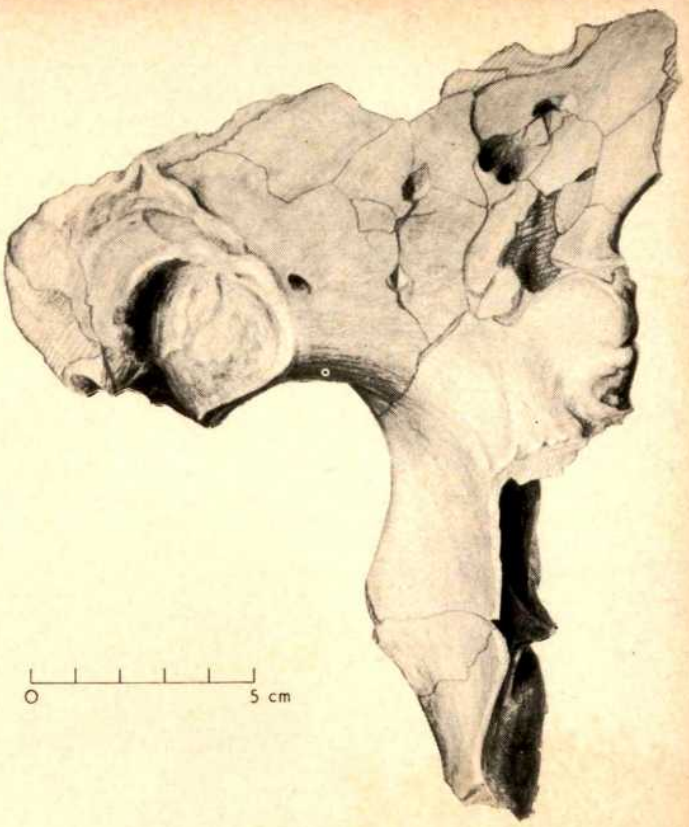

Fig. 4 Hip bone of Olduvai Hominid 28, pelvic surface. (Drawn by Audrey Besterman.)

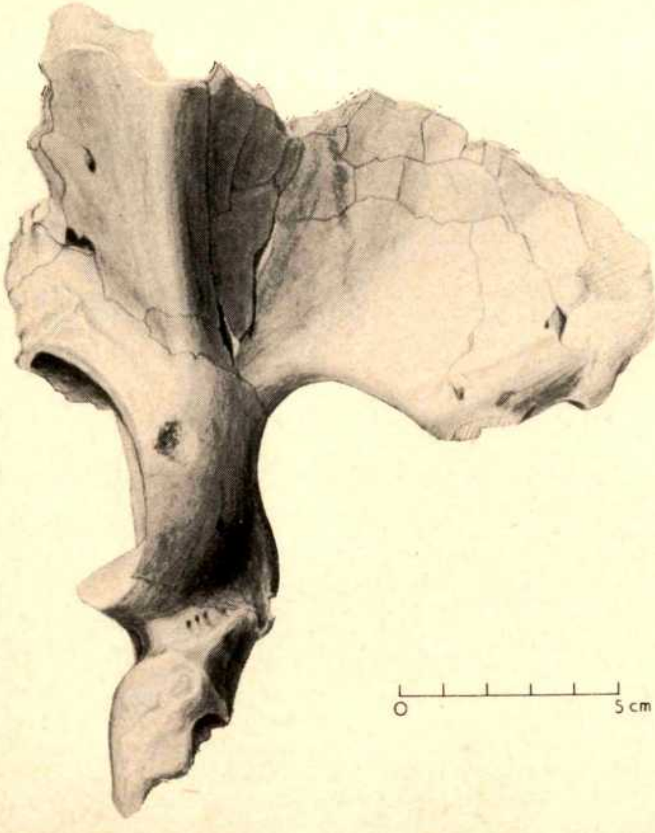

Fig. 3 Hip bone of Olduvai Hominid 28, gluteal surface. (Drawn by Audrey Besterman.)

Posteriorly the auricular surface is small, set low on the bone and is slightly obliquely placed. It is also extended laterally round the inferior border of the ilium. This extension of the auricular surface is at an angle of approximately 120° to the principal part of the surface and would seem to limit relative movements of the sacrum and ilium in a vertical direction. Behind the auricular surface the ilial tuberosity is large and very roughened for the attachment of extensive posterior sacroiliac ligaments. There is no pre-auricular sulcus.

Sexing the hip fragment proved difficult, partly because the pubis is missing. There are a series of contradictory features such as a general robusticity (male), wide sciatic notch (female), large acetabulum (male), auricular surface small and obtuse (female), but, on balance, it seems more likely that it is female though the matter is still open.

An X-ray of the pelvic fragment disclosed several interesting features, some of which confirm the anatomical findings; for example, the stout horizontal iliac bar and the ischium are reinforced by coarsely woven internal trabeculae, and the vertical iliac bar is heavily buttressed with dense bone.

Functional Considerations

The combination of features that characterize the hip bone and the femur allows some functional conclusions to be drawn. These conclusions are strengthened if the two bones are assumed to belong to the same individual; anatomically they are not incompatible and both belong to the left side, and because they were found in close association in the deposit it would seem reasonable and economical to assume that they belong with each other. It is suggested therefore that:

(1) The strength of the vertical iliac pillar, to resist the pull of gluteus medius, gluteus minimus and tensor fascia lata, coupled with the femoral expansion for the lower attachments for gluteus medius and minimus muscles, suggests that the alternating pelvic tilt mechanism of striding bipeds was well developed.

(2) The length and strength of the horizontal iliac bar, coupled with well marked attachments for gluteus maximus (on both hip bone and femur) and the hamstring muscles, indicate a powerful hip extensor mechanism for returning the trunk to the erect position and/or raising the trunk (as in walking uphill or climbing).

(3) The impressions for the iliofemoral ligament on both hip and femur suggest that the pelvic rest mechanism of advanced bipeds was fully developed and that the centre of gravity of the body was placed behind the line joining the rotation centres of the two hip joints.

(4) The rugged area for the attachments of the sacroiliac ligaments shows that the weight of the upper part of the body was being transferred to the pelvis by way of the sacral suspensory mechanism familiar in upright bipeds.

(5) The attachments of ilio-psoas and rectus femoris muscles indicate the power of hip flexion, and the rectus femoris muscle coupled with vastus medialis and lateralis muscles indicate that powerful extension of the knee was possible.

In summary there seems little doubt that Olduvai Hominid 28 was a habitual upright biped. Whether bipedalism in this form was as efficient as that of modern man will not be determined until these bones have been reconstructed and some of their special features fully explained in biomechanical terms, that is, the extremely strengthened vertical pillar, the medial rotation of the ischium and the like.

Comparative Anatomy

Comparisons have been made with a series of modern human femora and with the following.

(1) Originals: Trinil femora (I–VI); Rhodesian femora; Tabūn I femur; Olduvai Hominid 20 femur; and the Skhul IX femur.

(2) Casts and descriptions: Choukoutien femora; Krapina femora (1049 and II); Swartkrans femora; Spy II femur; Skhul IV femur; and the Kanjera femur.

Comparisons have also been made with a series of modern human hip bones and with the following pelvic remains.

(1) Originals: Rhodesian; Tabun.

(2) Casts: Swartkrans; Sterkfontein; Makapansgat; and Kromdraai.

Although some of the individual anatomical features of both the femur and pelvic fragment of Olduvai Hominid 28 can be matched in the comparative material, there is no doubt that it is only with the femora of the Choukoutien group of *Homo erectus* that the combination of features of the femur of Olduvai Hominid 28 can be closely paralleled. The combination of features of the Olduvai Hominid 28 pelvis are, however, so far unmatched in the comparative material studied.

It is established beyond reasonable doubt that the Choukoutien femora are part of the same assemblage as the Choukoutien *Homo erectus* cranial and dental remains[3] and can be assigned to the Middle Pleistocene[5]. In the meticulous descriptions of the Choukoutien postcranial remains, Weidenreich makes plain (1) that the femora must be attributed to a member of the genus *Homo*, and (2) that they are specifically distinct from the femora of *Homo sapiens*. On these grounds the bones were attributed, with the cranial and dental remains, to "*Sinanthropus pekinensis*". In his summary Weidenreich lists a number of features that he states are specific for this taxon. It is of interest to compare these features with the corresponding features of Olduvai Hominid 28 (Table 1).

Of these points, five agree completely, three are in partial agreement (mostly because of lack of evidence) and the sole point in disagreement is subject to considerable anatomical variability.

Table 1 Comparison between *Homo erectus pekinensis* and Olduvai Hominid 28

Homo erectus pekinensis	Olduvai Hominid 28
(1) Straightness of the shaft (that is, lack of marked A/P bowing)	Agrees
(2) The distal position of the least breadth of the shaft	Agrees
(3) Convexity of the medial border of the shaft	Agrees
(4) Pronounced platymeria of the subtrochanteric region combined with angularity (medial and lateral cristae)	Agrees
(5) (i) Development of a hypotrochanteric tubercle at the base of the greater trochanter	(i) Uncertain
(ii) The direct continuation of the hypotrochanteric crest into the greater trochanter	(ii) Agrees
(6) Absence of linea intertrochanterica and linea pectinea	Disagrees
(7) Extraordinary thickness of the wall of shaft and the neck combined with the narrow calibre of the medullary canal	Unusual neck thickness present, walls of moderate thickness, canal of moderate calibre
(8) Diffuse arrangement of the trajectorial system of the upper end combined with a tight-meshed and coarse cancellous substance	Specimen incomplete, but radiographic evidence is not inconsistent

Thus the group of features said by Weidenreich to be specific for Choukoutien *Homo erectus* are shared in large part by Olduvai Hominid 28 and are not found together in *Homo sapiens*. Furthermore, all the metrical features quoted by Weidenreich for Choukoutien *Homo erectus* fall within the range of variability quoted by him for *Homo sapiens*; but the important point made by him (before the advent of multivariate statistics in the assessment of affinity) was that it is the combination of features in Choukoutien *Homo erectus* that differs from the combination of features in *Homo sapiens*.

The femora that must be considered closely are the six femora from Trinil, Java[2,6–11]. It is primarily on these bones that there rests the widely held view that the lower limb of *Homo erectus* differed little from that of modern man, a view that depends in turn on the contemporaneity of the femora with the Trinil calotte, their proper attribution to a Middle Pleistocene date, and a morphological appraisal that considers these femora to be essentially sapient.

Through the kindness and courtesy of the director of the Leyden Museum I have been able to re-examine the Trinil femora both anatomically and radiologically. The preliminary results of this examination reaffirm that these femora have no significant anatomical, radiological or metrical features that lie outside the known range of variation for modern man, nor do they show any combination of features that constitutes a taxonomically or functionally significant morphological pattern. Further work is in progress, in conjunction with Miss Theya Molleson, of the British Museum (Natural History), in order to try to clarify the position by reviewing the evidence for the supposed provenance of the Trinil femora, and by reassessing their relative and absolute dating.

The Olduvai Hominid 28 femur clearly bears remarkable similarities to the well established *Homo erectus* femora from Choukoutien, anatomically, metrically (Table 2) and radiologically. At the same time the Olduvai Hominid 28 pelvic fragment shows a number of anatomical and radiological features that distinguish it from modern sapient pelves, but

* Reconstructed.

there are no known examples of *Homo erectus* pelvic remains from elsewhere with which to make comparisons.

It seems reasonable therefore to suggest that the morphological affinities of Olduvai Hominid 28 lie with *Homo erectus* from Choukoutien and that it should be attributed to this specific taxon. Only a full re-examination of the morphology and dating of the Trinil femora may enable the taxonomic position of this material to be established because they appear, perhaps as they always did, to have little in common with the *Homo erectus* femora from Choukoutien.

I thank Mrs Mary Leakey for allowing me to examine this material and Dr W. G. S. Hopkirk (Nairobi Hospital) and Dr Alan Walker (Department of Anatomy, University of Nairobi) for their help.

Spatial Discrimination in the Cytoplasm during Microtubule Morphogenesis

J. B. TUCKER
Department of Zoology, The University, St Andrews, Fife

Patterns of microtubule formation and breakdown in the ciliate *Nassula* provide some indications of the ways in which the deployment of substances influencing microtubule assembly is related to control of tubule growth.

DETAILS of microtubule distribution during the fission cycle in the ciliate *Nassula*[1–6] provide striking examples of how the precise spatial and temporal controls of assembly and breakdown of several microtubular organelles can be exercised simultaneously within a single cell. These findings raise fundamental issues concerning control of the ways in which microtubule precursor protein subunits, and other substances affecting microtubule stability, encounter the sites where tubules are growing or dissociating.

It is generally supposed that structural molecules are synthesized on ribosomes distributed throughout the cytoplasm and that these, and all other molecules influencing the growth and stability of organelles, reach their sites of action by random diffusion through the cytoplasm. This supposition has never been seriously challenged. It seems especially reasonable because several structural molecules, microtubule subunits included[7], self-assemble *in vitro* to form structures identical in many respects with those developing *in vivo* when this assembly is seeded by portions of the structures in question. In addition, there are indications that, in some cells, the distribution and form of certain nucleating sites define the positioning of the microtubules which grow out from them *in vivo* by providing sites which seed tubule assembly[3,4,8]. The positioning of these nucleating sites is probably crucial to the control of the number and location of microtubules. This article is not concerned with how nucleating sites act, or how they are distributed, but with the localization of microtubule subunits, and any other molecules influencing their assembly, at the sites where assembly or dissociation of these subunits is occurring. Some of the morphogenetic events described here, which are probably paralleled in other cells, cannot be entirely accounted for by the interaction of randomly diffusing molecules with a set of nucleating sites and mature and growing microtubular organelles.

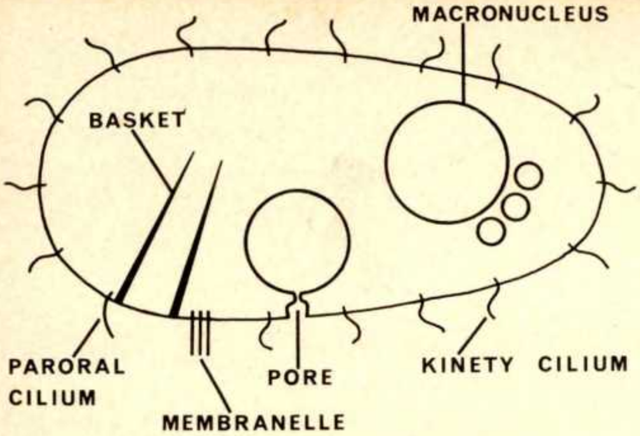

Fig. 1 Diagrammatic median longitudinal section of an interfission *Nassula*. Its anterior end is to the left and its ventral surface towards the bottom of the figure.

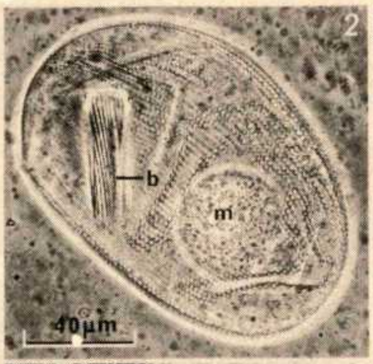
Nassula during the Cell Cycle

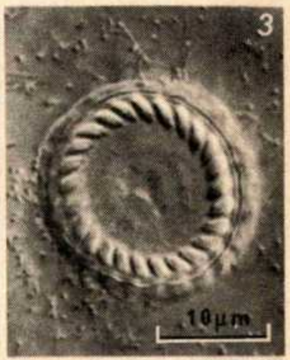
Nassula possesses a single macronucleus (Fig. 2, *m*) with three adjacent micronuclei. Most of the other large organelles are attached to the pellicle (Fig. 1). The contractile vacuole pore (Fig. 5, *c*) is a pellicular invagination connecting to the vacuole. A feeding organelle, the cytopharyngeal basket, consists largely of a circular palisade of rod-shaped microtubule bundles (Figs. 2, 3 and 4). A row of paroral cilia (*p*) flanks the oral opening (*o*) and a row of ciliary membranelles (*x*) passes just over halfway around the organism (Fig. 5). Rows of cilia called kineties extend from one end of the organism to the other; basal bodies in the same kinety are linked by bands of microtubules.

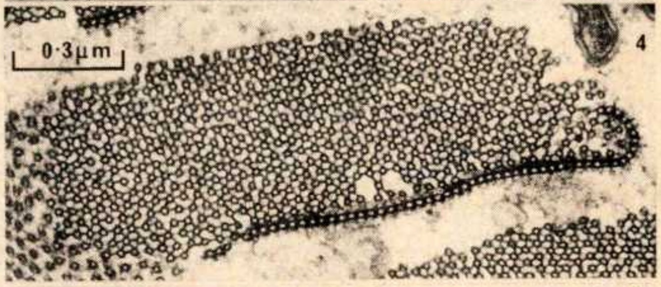
Many of the changes in microtubule organization during binary fission, summarized here with the aid of Fig. 6, occur simultaneously. At 20° C all take place within 2 h of the start of fission, except the growth of new baskets, which continues for another 2.5 h. The old basket (1) detaches from the pellicle and two new baskets (2) develop. In each region where a new basket develops, a set of new rods initially forms a series of short rows, which align to form a single long row, which then rolls up to form a circular palisade.

Spindle tubules form and break down inside the macronucleus (3) and three micronuclei (4) while nuclear membranes remain intact. Morphogenesis of all the other microtubular organelles considered here occurs in a common continuously streaming cytoplasm. No membranes partition this cytoplasm to prevent molecules diffusing between these organelles. While nuclei divide, three types of tubule arrays develop just before, and break down shortly after, they are spatially associated with changes in cell shape or movement of cytoplasmic structures. A reticulum of microtubules (5) interconnects growing cytopharyngeal rods as they roll up to form two new baskets (2). Simultaneously microtubular strands (6) contact contractile vacuole pores as pores move posteriorly for about 30 µm, while a microtubular girdle (7) forms at the base of the cleavage furrow. Also, new microtubules are augmenting the bands (8) to link permanently new and old kinety basal bodies.

If tubule subunits in each type of array differ from those in other arrays, assembly of appropriate amounts of each species of subunit at the sites, where only they can assemble, may be largely determined by the amounts synthesized. Even if subunits are synthesized more or less randomly throughout the cytoplasm, approximately equal quantities of a subunit species will by random diffusion encounter each appropriate assembly region. But if the tubules in these several arrays are of identical composition, control of the distribution of subunits to assembly sites must be more refined; at least as refined as that which controls the morphogenesis of cilia, basal bodies and cytopharyngeal microtubules. There are important instances involving these structures where initially identical tubules develop in one cytoplasmic region and simultaneously break down in another. For example, old cytopharyngeal baskets (1) gradually break down for 1 h while new ones (2) develop. Even some new cytopharyngeal rods (9) break down while the remainder continue lengthening; these are errant rods which have not been included in a new circular palisade during rolling up. Neither old baskets nor errant rods are enclosed in vacuoles while they break down. Paroral cilia and their basal bodies (10) develop about 1 h before any of the others, while only the cilia of the old membranelles (11) break down and the old kinety cilia (12) remain intact. Subsequently new membranelles (13) and kinety cilia (14), and new cilia forming on old membranelle basal bodies (11), all develop at about the same time. It is difficult to account for these events if it is assumed that tubule







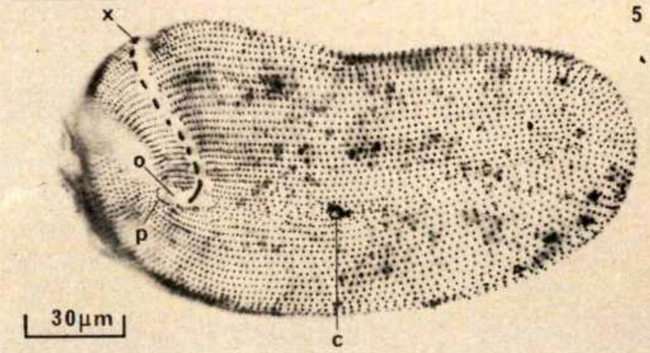


Fig. 2 An interfission *Nassula* after cold ethanol digitonin treatment[9] which dissolves most cytoplasmic components and leaves a pellicular ghost enclosing the cytopharyngeal basket (*b*) and the macronucleus (*m*). The top of the basket, which is attached to the pellicle, is towards the top of the figure. Phase contrast.

Fig. 3 The circular palisade of rods in a living *Nassula* at the top of a cytopharyngeal basket, viewed from above. Numerous cilia are also shown. Nomarski interference contrast.

Fig. 4 A microtubular cytopharyngeal rod in cross-section. Electron micrograph.

Fig. 5 The ventral surface of an interfission *Nassula* with its anterior end to the left and its left side towards the top of the figure. The pellicle is stained with silver[10] around the rim of the contractile vacuole pore (*c*) and where it is penetrated by cilia. A row of paroral cilia (*p*) flanks the oral opening (*o*). A row of ciliary membranelles (*x*) and numerous rows of kinety cilia are also shown. Bright field.

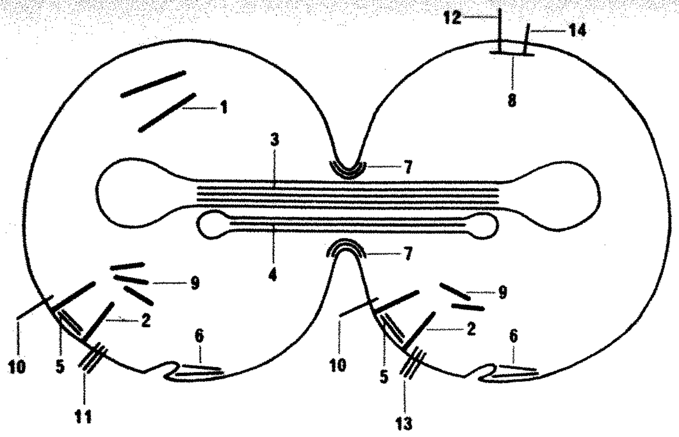

Fig. 6 Schematic diagram of a median longitudinal section of a dividing *Nassula* showing the positions of the majority of its microtubular organelles. The organism is oriented as in Fig. 1. For clarity contractile vacuoles have been omitted, and only two kinety cilia and one of the three micronuclei have been included. The lines indicating the positions of microtubular arrays and organelles also show the orientation of the longitudinal axes of the tubules but provide no indication of the numbers of tubules involved. Old cytopharyngeal basket, (1); new cytopharyngeal basket, (2); macronuclear spindle, (3); micronuclear spindle, (4); microtubular reticulum associated with rolling up of new cytopharyngeal rods, (5); microtubular strand associated with posteriorly directed movement of contractile vacuole pore, (6); microtubular girdle at the base of the cleavage furrow, (7); microtubular band linking kinety basal bodies, (8); errant rods, (9); paroral cilium, (10); old ciliary membranelle, (11); old kinety cilium, (12); new membranelle, (13); new kinety cilium, (14).

subunits are synthesized more or less randomly throughout the cytoplasm, and that they, and all agents which affect tubule stability, reach tubules and tubule nucleation sites by simple diffusion through the cytoplasm. There must be special ways of concentrating these materials in discrete cytoplasmic regions without partitioning these regions off from the remainder of the cytoplasm by membranes. Analyses of cytopharyngeal morphogenesis, now being undertaken, suggest ways in which such concentrations may be achieved.

Cytopharyngeal Microtubules

When dividing organisms are immersed in aqueous solutions of colchicine (5 mg/ml.), assembly of cytopharyngeal tubule subunits is completely inhibited. Tubules subsequently attain normal lengths after assembly has been delayed for 1 h if organisms are returned to their normal culture medium (water). Immersion in aqueous solutions of cycloheximide (5 μg/ml.) greatly reduces the rate of subunit assembly, and when assembly ceases the tubules are much shorter than is normally the case. In some experiments assembly was delayed by using colchicine for 1 h just after assembly had started, and then colchicine was leached out of the organisms while simultaneously cycloheximide was applied. Tubules finally attained the same lengths as they did in organisms in which subunit assembly had proceeded normally for the first hour of development before cycloheximide was administered. Thus there is an increase in the amount of tubule subunit assembly occurring in the presence of cycloheximide following a 1 h delay of assembly induced by colchicine. Hence cycloheximide probably does not interfere directly with assembly in a marked fashion, and is almost certainly inhibiting assembly by blocking synthesis of proteins, possibly tubule subunits, which is occurring while subunits assemble. Cycloheximide acts in this manner during flagellar regeneration in *Chlamydomonas*[11]. While assembly is most sensitive to cycloheximide in *Nassula*, ribosome-bearing cisternae of endoplasmic reticulum are clustered around the tips of tubules where subunit assembly occurs. Thus tubule subunits, or materials which stabilize their assembly, may be synthesized on particular ribosomes and not released until the ribosomes are very close to the tubule assembly points.

Errant rods move away from new baskets before breaking down. If organisms are immersed in aqueous solutions of vinblastine sulphate (10 μg/ml.) this movement does not occur and errant rods remain intact. The agents provoking breakdown have probably not been inactivated, for the more lengthy breakdown of the much larger old baskets still proceeds under these conditions. Thus it seems that these agents are strictly localized in particular cytoplasmic regions. To account for the spatial discrimination involved in selective breakdown of this kind there is little alternative but to postulate the operation of sophisticated procedures. For example, breakdown of errant and old rods, but retention of new baskets, could be accomplished if the agents promoting breakdown have a relatively short active life, and are only present and bound to the nuclear envelopes for about 90 min from the start of fission. Errant and old rods may contact the envelopes of the centrally positioned nuclei but new short baskets attached to the pellicle cannot do so (Fig. 6). It is also necessary to postulate that the agents are only released from nuclear envelopes when contacted by tubules, to which they attach, and then progressing along tubules cast off subunits behind them, while remaining attached to the contiguous tubule remnants until their deactivation is induced by fragmentation of the final portions of tubules. It is significant that *in vivo* cytopharyngeal tubules break down progressively from their tips[3].

Experiments to test these hypotheses are in progress. In the meantime it is worth bearing in mind the possibility that the distribution of molecules involved in organelle morphogenesis may often be extensively governed by their being bound to larger structures up to the point at which they interact with a mature or growing organelle.

Other Cells

To what extent are the events described here typical of cells generally? The large size of some of the organelles involved is certainly unusual, but the information required to specify that a bundle of about 10 microtubules about 10 μm long grows out from a particular site at a particular phase of the cell cycle need not be greatly augmented to ensure that the development of a bundle of about 1,000 tubules about 100 μm long is equally precisely controlled. It is also worth noting that very precisely controlled patterns of simultaneous microtubule formation and breakdown are known to occur in the cells of certain multicellular organisms, for example[12], and for spindles, at least, we know that control of tubule deployment is very exact.

Egg cytoplasm differentiates into regions of different composition sometimes characterized by distinct groupings of ribosomes and other organelles[13]. Patterns of egg cytoplasm differentiation are spatially related to patterns of cell differentiation in embryos. Mechanisms defining cytoplasmic patterns in eggs may be similar to those controlling microtubule arrangement in cells generally.

I thank the Science Research Council for a research grant, Miss C. T. Graff for conducting some of the experiments, and the *Journal of Cell Science* for permission to reproduce Fig. 3.

Atmospheric Total Ozone Increase during the 1960s

NAMIAS[1] has postulated that sea-air interactions on a regional basis, and not necessarily air pollution, volcanic activity, or solar intensity variations, may have caused the cooling trend that was observed in numerous areas of the world during the past decade[2,3]. In particular, he attributed the United States temperature anomaly, that is, lower than normal winter temperatures in the eastern two-thirds of the county, and higher than normal winter temperatures in the west, to intensification of the Rossby wave at the 700 mbar level. This intensification strengthens the ridge over western North America and deepens the trough to the east, thus increasing the frequency of deployment of Arctic air masses into the eastern United States. Namias attributed the change in the character of the Rossby wave to abnormal cyclonic activity that occurred in the winter atmospheric circulation over the North Pacific, the surface waters of which were unusually warm during the 1960s.

Because the effects of a deepened 700 mbar trough over the eastern United States might reasonably be expected to extend to higher altitudes, we considered the possibility that the increased southward flow of air in the troposphere and low stratosphere led to an average increase in total ozone amount over central and eastern North America during the 1960s. Ozone is transported poleward from the equatorial stratosphere source region in the winter hemisphere, before it descends to lower levels[4]. To determine whether an increase in total ozone occurred, we analysed data obtained during the decade 1961 to 1970 at Edmonton, Goose Bay, and Toronto, in Canada, and at Boulder, Bismarck, Green Bay, Caribou, Bedford, Nashville, and Tallahassee, in the United States. The periods of record ranged from 7 to 10 years for all stations except Tallahassee, where observations were made for only 5 yr. At eight of the ten stations, we found statistically significant increases in ozone that varied between 4.4% per decade at Goose Bay, to 8.8% per decade at Nashville, with an average increase for the eight stations of 5.6% per decade. At Green Bay and Toronto, although the calculated trends in ozone were not found to be statistically significant, they produced small positive values, 2.0% and 3.5% per decade, respectively.

To ascertain whether the trough deepening described by Namias extended into the low stratosphere, the geopotential heights of the 200, 100, and 50 mbar pressure surfaces at two stations—Caribou and Nashville—were investigated for the period January 1961 to August 1970. The results of the analysis suggest to us that trough intensification occurred at both stations, particularly during February and March and to a lesser extent in September, October, and November. During other months of the 10 year period, progressive weakening of the trough occurred.

Our total ozone data analyses also yielded statistically significant ozone increases during the 1960s at Dobson spectrophotometer stations distant from the North American continent. At Mauna Loa Observatory in Hawaii, the upward trend was 2.5% per decade, while at Huancayo, Peru, the trend was 6.0%. Subsequent analyses of data from several foreign stations (Fig. 1) confirmed that increases in ozone were not confined to the North American region, but were also characteristic of other areas of the world.

Fig. 1 shows mean monthly total ozone deviations from monthly normals, based on the periods of record indicated, for seven stations in the northern and southern hemispheres. The ozone monthly means were calculated, in most instances, from observations during 25 or more days per month; in isolated cases, however, the means were determined from as few as 10 days of observations. The ozone trend lines were fitted to the data by the least squares method. Table 1 summarizes the results.

Note that the calculated rates of ozone increase range from 2.4±0.6% per decade at Mauna Loa Observatory in Hawaii, to 10.0±0.4% per decade at Kodaikanal in India. Errors given with the trend figures are computed probable errors. In calculating the trends we have assumed that the calibration levels of the spectrophotometers, operated at the stations listed in Table 1, remained constant in time. Using the criterion that the sign of the ozone trend is significant, provided that it does not change within the range of ±3 probable errors, the

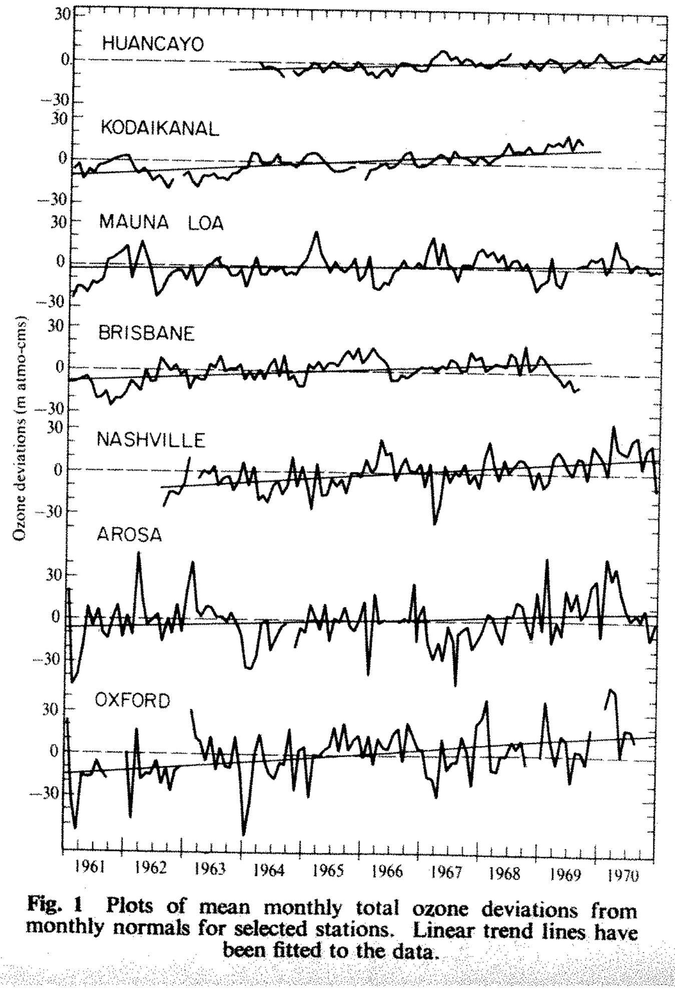

Fig. 1 Plots of mean monthly total ozone deviations from monthly normals for selected stations. Linear trend lines have been fitted to the data.

data clearly indicate that statistically significant increases in total ozone amount were detected at the stations listed in Table 1.

Table 1 Summary of the Data Analyses presented in Fig. 1

Station	Lat., long.	Mean O_3 in m atmo-cms†	% O_3 increase per decade*
Huancayo, Peru	12° 03′ S, 75° 19′ W	262	6.0 ± 0.4
Kodaikanal, India	10° 14′ N, 77° 28′ E	257	10.0 ± 0.4
Mauna Loa, Hawaii	19° 32′ N, 155° 35′ W	276	2.4 ± 0.6
Brisbane, Australia	27° 28′ S, 153° 02′ E	289	6.6 ± 0.6
Nashville, USA	36° 15′ N, 86° 34′ W	332	8.8 ± 0.7
Arosa, Switzerland	46° 46′ N, 09° 40′ E	333	4.1 ± 1.0
Oxford, England	51° 45′ N, 01° 11′ W	354	8.9 ± 1.0

* Extrapolated from the periods of record shown in Fig. 1.
† The unit "m atmo-cms" or "milli-atmo-cms" is used to denote the total amount of ozone in a vertical column of the atmosphere, expressed as the thickness of the ozone layer at STP, assuming that the ozone is separated from the rest of the air.

Although additional data analyses yielded increases in ozone at most stations investigated, the results were not always statistically significant. For example, a small but statistically insignificant increase in ozone of $1.1 \pm 0.9\%$ per decade was calculated for Aspendale, Australia (38° 02′ S, 145° 06′ E). We also analysed data obtained at Tateno in Japan (36° 03′ N, 140° 08′ E), and Vladivostok in Siberia (45° 07′ N, 131° 54′ E). Both these stations lie near a region that, according to Namias, experienced a deepening of the 700 mbar trough during the past decade similar to the trough intensification that occurred over eastern North America. Although a positive trend in total ozone of $6.2 \pm 3.3\%$ per decade was computed for Vladivostok, we cannot classify this as significant under the criterion that it did not change sign within the range of ± 3 probable errors. For Tateno, on the other hand, a downward trend in ozone was calculated, also statistically insignificant, and of magnitude $-3.4 \pm 1.3\%$ per decade.

The tentative linear analyses of the North American total ozone data, as well as the analyses of the data from foreign stations shown in Fig. 1, suggest that an increase in total ozone occurred in many areas of the world during the past decade. This increase cannot be interpreted as an apparent ozone increase that has arisen because of errors in measurement associated with changing atmospheric turbidity. The fundamental method of measuring ozone with Dobson ozone spectrophotometers[5], using wavelength pairs A(3055 Å, 3254 Å) and D(3176 Å, 3398 Å), is highly insensitive to scattering of solar radiation by particulate matter because, through the subtraction of two nearly equal terms, the scattering term that appears in the equation from which total ozone amounts are calculated is rendered negligibly small. The possibility that the computed rates of ozone increase are due to long term drift in spectrophotometer calibrations should, however, not be discounted. We recently compared the calibration level of our Caribou spectrophotometer with that of a standard spectrophotometer maintained at Boulder, Colorado, and found a drift in the calibration of the Caribou instrument. The magnitude and direction of the drift are such as to account for about one-half of the 5.9% calculated rate of ozone increase per decade at Caribou. In June 1970, on the other hand, the Nashville spectrophotometer was brought to Boulder and compared with our standard instrument. The intercomparison tests showed that the calibration level of the Nashville spectrophotometer did not change by more than 2% during 8 years of operation. Thus, the deduced 8.8% per decade increase in ozone at Nashville cannot be attributed, in large measure, to drift in instrument calibration.

A more comprehensive analysis than that presented here is needed to determine whether a global increase in atmospheric total ozone occurred during the past decade, or whether ozone increases in certain areas of the world were compensated by decreases in other areas. Such an analysis should not only involve data from the worldwide network of total ozone observatories, but should also take into account the calibration histories of the instruments with which observations were made. We are currently recalibrating our Dobson ozone spectrophotometers in an effort to determine the influence of drift in instrument calibrations on the accuracy of the North American ozone measurements.

The Huancayo station is operated in cooperation with the Instituto Geofisico del Peru.

Do Neutron Stars have an Ocean Surface?

This article draws attention to one of the more important unsolved problems concerning the qualitative nature of the outer layers of a neutron star. We refer to the likelihood of there being a vapour-liquid type phase transition, involving a major density discontinuity by a factor that could be as high as three or more, between the crust (in which starquakes are thought to take place) and the neutron superfluid below. The idea that such a phase discontinuity might exist is not new[1], but the question does not seem to have been taken seriously in recent years. This is due to the absence of discontinuities not only in the highly simplified but historically important equations of state of Harrison and Wheeler[2] and of Tsuruta and Cameron[3] which played such an important role in discussions of neutron star structure in the period extending up to the mid sixties, but also in the much more sophisticated equations of state which have been published in recent years, such as those of Langer, Rosen, Cohen and Cameron[4], Bethe, Borner and Sato[5], and Wang, Rose and Schlenker[6].

We wish to make clear that the issue is still far from closed and that the existence of a major discontinuity is not only possible but even probable. The general problem of vapour-liquid type phase transitions in many fermion systems has recently been the subject of a reappraisal by Baker and Kahane[7]. They give naive but cogent reasons for expecting the existence of a discontinuous phase transition in any system of fermions where the interparticle forces are predominantly attractive at medium ranges but repulsive at short ranges: conditions which are believed to hold in a real neutron gas. This simple reasoning cannot, of course, be conclusive (the chief element of doubt being in the question of how, when the forces have a complicated anisotropic form, one defines "predominantly"), but on the other hand, according to Baker and Kahane, the accuracy and convergence properties of the Brueckner-type expansion calculations, on which most of the present day continuity-free equations of state are based, are necessarily questionable in the neighbourhood of a real discontinuity. Furthermore, the most recent calculation along traditional lines, that of Baym, Bethe and Pethick[8], predicts a first order phase transition (although their density is discontinuous by a very small fraction, quite unlike the order of magnitude change which we have in mind). What is clear is that considerably more elaborate techniques will be needed to decide conclusively whether or not neutron star matter has a large first order phase discontinuity between sub-nuclear and nuclear densities.

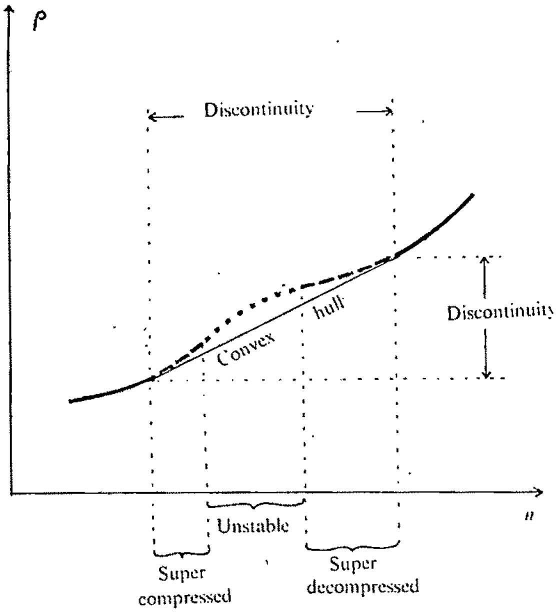

Fig. 1 Typical form of an equation of state with a first order phase transition.

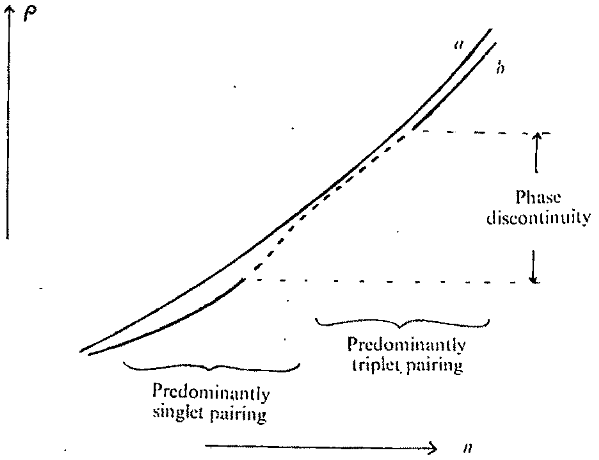

Fig. 2 Sketch illustrating (on an exaggerated scale) the qualitative form of the correction to the equation of state which can be expected to result from taking Cooper pairing energy into account. The convex curve *a* represents the uncorrected equation; the partly concave curve *b* represents the corrected equation.

It is worth emphasizing that we are not suggesting that the best present day equations of state are grossly unreliable in the sub-nuclear to nuclear density range (10^{11} to 10^{14} g cm^{-3}) as they are at higher densities where hyperons and other high energy phenomena are important. The point is that quite a small alteration in the basic equation of state—which consists of an expression for the ground state energy density ρ as a function of baryon number density *n*—can introduce or remove a large density discontinuity. To make this clear we recall the standard principle (see, for example, ref. 2) that the necessary and sufficient condition for the absence of a discontinuity is that the curve of ρ against *n* be everywhere convex downwards. States where the curve is concave are locally unstable, and states where the curve is convex, but within and not on the convex hull, are only metastable (corresponding to supercompressed or superdecompressed states). Hence no states off the convex hull can exist in a stationary situation and nearly all methods of approach predict that the ρ–*n* curve is almost straight in the density range from 10^{11} to 10^{14} g cm^{-3} so the distinction between convexity and concavity is a fine one. For example, the ρ–*n* curve of Baym, Bethe and Pethick deviates from a straight line over the range 1.3×10^{14} to 3.9×10^{14} g cm^{-3} by an amount corresponding to at most about 1.2 MeV per baryon. This means that energy corrections of this order of magnitude, which corresponds to about 10% of the total non-rest mass energy, would be sufficient to introduce a density discontinuity over a comparable range.

No one would claim that even the best present day equation of state calculations are reliable to within one MeV per baryon. Corrections of this order can come from many subtle effects such as three body interaction energies and Cooper pairing energies. Moreover, it would appear that the contribution from this latter effect is indeed of such a form as to introduce a concavity into the ρ–*n* curve, because the curve of pairing energy density against baryon number density can itself be expected to have a concavity due to the changeover from relatively strong singlet pairing at sub-nuclear densities to relatively weak triplet pairing at nuclear densities[9]. It may well be that this effect is not quite large enough, or that it is cancelled out by other fine corrections. Nevertheless it seems at least very likely that this effect really does introduce a significant phase discontinuity.

Such a discontinuity would be in many ways analogous to the terrestrial ocean surface, and as such might admit gravity waves, provided that the mechanism (such as a starquake) by which they were generated could release sufficient energy to dissolve the crystal structure at the base of the crust.

We thank James B. Hartle for useful discussions.

The Hubble Constant and X-rays from Galaxy Clusters

X-RAY measurements and limits on the Coma and Virgo clusters of galaxies have been said to limit the mass of hot gas in them to 2% of the amount required for stabilization according to the virial theorem[1]. Such a conclusion is strongly dependent on the value of the Hubble constant H_0. The linear diameter of the cluster D and the cluster mass M, estimated by the virial theorem, each vary as H_0^{-1}. Therefore, the density ρ has the dependence $\rho \sim H_0^2$. The predicted X-ray flux F from this gas is $\sim \rho M/R^2$, where R is the distance to the cluster. R varies as H_0^{-1}. We therefore have the relation

$$F \sim H_0^3 \tag{1}$$

Meekins *et al.*[1] appear to have used the value $H_0 = 95$ km s^{-1} Mpc^{-1} found by van den Bergh[2], because they took $R = 70$ Mpc. If Abell's value[3] $H_0 = 47$ is used, the predicted flux is reduced by a factor of 0.12. A reduction of H_0 to a value as low as 20 is not inconceivable. Although clumpiness increases F/M^2, the presence of helium as a mass fraction f reduces F for fixed M in the ratio $(1-\frac{1}{2}f)$.

Meekins *et al.* measured a flux of 0.03 photons cm^{-2} s^{-1} almost entirely in the range 3–17 Å, and from other wavelength channels were able to state that the gas temperature exceeds 8×10^6 K. For a flat counter response I have determined from standard bremsstrahlung formulae[4] that it would take 2.6×10^{47} g of hydrogen at this temperature, uniformly distributed in a sphere of diameter 4 Mpc at the adopted distance of 70 Mpc, to produce this flux. This is four times the mass limit given by Meekins *et al.*[1], and is in clear disagreement because they gave a diameter of 5 Mpc and the actual counter response rises as the bremsstrahlung spectrum falls. A recalculation by Dr Meekins (private communication) based on the original assumptions and actual counter efficiency has confirmed that the mass estimate is higher than originally stated and in fact is increased to 7×10^{47} g. On this basis, a value

$$H_0 = 38 \text{ km s}^{-1} \text{ Mpc}^{-1} \tag{2}$$

would suffice to give agreement with the virial theorem for the Coma cluster. Those who are sure, as I am not, that clusters of galaxies are stabilized by ionized gas may interpret the X-ray measurement of Meekins *et al.* as a measurement of H_0.

Mercury in Water of the Tidal Thames

WE have developed a method for the determination of traces of mercury, and have applied it to the tidal reaches of the River Thames. This article reports our observations of the concentrations of mercury and its partition between dissolved forms and that adsorbed on suspended particulate matter.

There is a background concentration of about 0.02 μg/kg mercury in natural waters[1–3], and some recent results[4] showed values of 0.009–0.021 μg/l. for essentially dissolved mercury in sea and river water. In regions of mercury mineralization[5], however, up to 100 μg/kg has been reported. Similar amounts are found as a result of industrial pollution[1]. For this study we chose sampling sites ranging from river water at Teddington to seawater at Southend with intermediate stations at Woolwich and Gravesend. The effluent from the Northern Outfall Sewage Works which provides a major input into the Thames[6] was also examined. To achieve uniform sampling conditions all samples were collected by officers of the Port of London Authority on one day (May 24, 1971) 0.5 h after the afternoon high water at each station. Mercury was determined in whole and in filtered water and the mercury associated with the particulate matter found by difference.

The concentration of mercury in filtered water was low in the river water at Teddington and the seawater at Southend, and higher at Woolwich and Gravesend (Table 1). The level of dissolved mercury in the Northern Outfall effluent (0.515 μg/kg) suggests that some mercury may be held in solution as organic complexes. At all stations most of the mercury was associated with the particulate matter. In waters of high chloride concentration 96–98% of the total mercury was in this form, the proportion being lower in the river water (87%) and in the sewage effluent (82%). The concentration of mercury in the suspended particulate matter varied significantly with 1.8 mg/kg in the river water at Teddington, 9.6 mg/kg in the seawater and 4.3 and 4.9 mg/kg at Woolwich and Gravesend. The seawater may have been affected by effluent from the Southend outfall. Particulate matter in the Northern Outfall effluent contained 35 mg/kg mercury. The total concentration of mercury in the effluent (2.85 μg/kg) was about sixty times that in the river water at Teddington but is comparable with the slightly below 1 μg/l.[7] reported for the Hyperion outfall, Los Angeles. Thames estuary water is only slightly stratified[6] indicating a high degree of mixing, and the outfall is sited and operated to achieve a rapid dilution of the effluent.

Surface water was collected in a plastic container and transferred immediately to acid washed screw cap polypropylene bottles. For total mercury determination about 200 g was used. For dissolved mercury about 1 kg of water was filtered by pressure through a Whatman GFC filter, the collecting bottle

Table 1 Concentration of Mercury in Thames River Water

Miles from London Bridge	Station	Cl$^-$ (mg/l.)	Particulate matter (mg/kg)	Mercury found (μg/kg)			Calculated levels of mercury on particulate matter	
				Total	Dissolved	Difference	mg/kg	% of total
−18.5	Teddington	39	21.6	0.045	0.006	0.039	1.8	87
9	Woolwich	3,610	73.1	0.328	0.013	0.315	4.3	96
11.5	N. Outfall	142	66.0	2.85	0.515	2.34	35.5	82
27	Gravesend	10,030	89.9	0.446	0.009	0.437	4.9	98
43	Southend	16,480	8.2	0.082	0.003	0.079	9.6	96

washed free of particulate matter with distilled water, and the filtered sample replaced. (Only 200 ml. of the filtered Outfall water was used.) Both sizes of sample were weighed, made normal in sulphuric acid by adding 50% v/v H_2SO_4, and 0.05 normal in permanganate by adding 5% w/v $KMnO_4$ in water, then shaken for 1 h. This treatment dissolved elemental mercury, mercury salts, and organo-mercury compounds as Hg^{2+}. Excess permanganate and any MnO_2 formed were reduced by adding 30% H_2O_2 solution. A silver wire coil[8] freed of mercury by heating was added to each bottle and the bottles shaken overnight. Up to this stage the samples remained in their collecting bottles, thus minimizing contamination and losses of mercury. Each coil was removed from the solution, washed with water and acetone and dried in air. Optimum conditions for the recovery of mercury were determined using ^{203}Hg tracer. Mercury amalgamated with the silver was driven off by heating the coil to roughly 250° C in a silica tube. The mercury vapour was passed in a stream of nitrogen through a cell of 15 cm light path, in an atomic absorption spectrophotometer. The mercury atomic absorption peak was recorded on a strip-chart recorder and the amount of mercury present determined by comparison with the peak heights of calibration standards. Blanks of distilled deionized water and standards of Hg^{2+} added to distilled deionized water were run through the complete procedure with each set of samples. Interference by non-atomic absorption was found to be negligible during experiments using an intermediate distillation onto gold, but a deuterium arc background corrector was used in the determinations. For 1 kg samples the standard deviation of the blank was 0.0014 μg/kg and the coefficient of variation at the 0.050 μg/kg level was 1.8%. Particulate matter was determined from the increase in weight of the GFC filters used to filter the 1 kg samples after drying at 110° C. Chlorosity was determined by titration of a separate sample of water using silver nitrate.

Examination of additional samples taken at the Victoria Embankment (Cleopatra's Needle steps) at low water showed that the suspended particulate matter contained 5.0 mg/kg mercury and the deposited sediment 0.20 mg/kg mercury. Both samples were in contact with water containing 0.017 μg/kg dissolved mercury, the difference reflecting the proportions of fine particles in the two materials. Only 4% of the sediment passed through a 63 μm sieve. The level of 0.20 p.p.m. mercury is similar to values we have found in sediment samples from the outer Thames estuary, and to reported values for shales[1].

This study indicates that 82–97% of the mercury in tidal waters of the Thames is held on suspended particulate matter and that significant amounts of mercury are introduced in sewage effluent. Among aquatic organisms, filter feeders such as molluscs and tunicates are especially exposed to mercury in the particulate form, but as dissolved mercury is readily adsorbed onto particulate matter, the effects of mercury on photosynthesis and productivity of phytoplankton may be more important. Both these aspects of mercury accumulation warrant further investigation.

We thank N. M. Baker and J. A. Tetlow of the Port of London Authority for water samples.

The Oxfordshire Coalfield

THE discovery of eight coal seams of workable quality in the Geological Survey Apley Barn Borehole[1,2], sunk in 1960–61 near Witney, prompted the recent sinking of a second borehole (1970–71) near Steeple Aston, Oxfordshire. This borehole is situated between Bicester and Chipping Norton some 14 miles north-east of the Apley Barn Borehole (Fig. 1). The exact site is 825 yards (750 m) at 254° from St Peter's Church, Steeple Aston (National Grid Reference SU 4687 2586). The geophysical Bouguer anomaly gravity contour map shows that the borehole lies in the eastern part of a low density area where a thick sequence of light sedimentary rocks could be expected. It was thought possible that this anomaly could be due to a thickening of the Coal Measures sequence as a whole and that perhaps even Middle Coal Measures (with valuable coal seams) could be developed. In the event, however, this hope has not been realized, and although Upper Coal Measures were proved the borehole has shown that the low density anomaly feature must be due to a thickening of Devonian and/or older sediments.

The sequence proved in the Steeple Aston Borehole is as follows: Jurassic and Permo-Triassic rocks to 751 feet 3 inches (228.98 m), Upper Coal Measures to 2,003 feet 6 inches (610.67 m), intrusive igneous rocks to 2,545 feet 4 inches (775.82 m), Upper Devonian rocks to 3,172 feet 3 inches (966.90 m) then further intrusive rocks to a final depth of 3,199 feet 3 inches (975.13 m). Previously the Apley Barn Borehole had proved 820 feet 10 inches (250.19 m) of Jurassic and Permo-Triassic rocks, Upper Coal Measures (including eight seams totalling 27 feet of coal) to 3,968 feet 7 inches (1,209.62 m), Upper Devonian to 4,408 feet 4 inches (1,343.66 m) and Lower Devonian to a final depth of 4,941 feet 8 inches (1,506.22 m). In spite of the thinner sequence of Upper Coal Measures contained in the Steeple Aston Borehole, seven coal seams of workable quality more than 2 feet thick were encountered: (1) a 2 feet 2 inches seam base at 896 feet 6 inches, (2) a 2 feet 10 inches seam base at 925 feet 10 inches, (3) a 3 feet 5½ inches seam base at 957 feet 4½ inches, (4) a 2 feet 1½ inches seam base at 987 feet, (5) a 2 feet 8½ inches seam base at 1,479 feet 1½ inches, (6) a 7 feet seam base at 1,533 feet 5½ inches and (7) a 5 feet 5½ inches seam base at 1,997 feet 9 inches. These seams, which total 25 feet 9 inches in thickness, are being analysed in detail by the National Coal Board. A good correlation exists between the two boreholes, the measures from 751 feet 3 inches (228.98 m) to 1,130 feet 6 inches (344.28 m) in the Steeple Aston Borehole being correlated with the Burford Coal Group which occurs between 1,475 feet (449.28 m) and 1,928 feet 5 inches (587.78 m) in the Apley Barn Borehole, the measures from 1,130 feet 6 inches (344.28 m) to 1,393 feet 3 inches (424.36 m) being correlated with the Crawley Group at 1,928 feet 5 inches (587.78 m) to 2,600 feet (792.48 m) in Apley Barn, the measures from 1,393 feet 3 inches (424.36 m) to 1,533 feet 5½ inches (467.40 m) with the Witney Coal Group at 2,600 feet (792.48 m) to 2,872 feet 4 inches (875.49 m) in Apley Barn and the measures from 1,533 feet 5½ inches (467.40 m) to 2,003 feet 6 inches (610.67 m) with the Arenaceous Coal Group at 2,872 feet 4 inches (875.49 m) to 3,968 feet 7 inches (1,209.62 m) in the Apley Barn Borehole[2]. Farther afield the Burford Coal Group correlates with the Radstock Group of the Somerset Coalfield, the Witney Coal Group with part of the Farrington Group of Somerset and the Arenaceous Coal Group with the Mangotsfield Group of Somerset and the

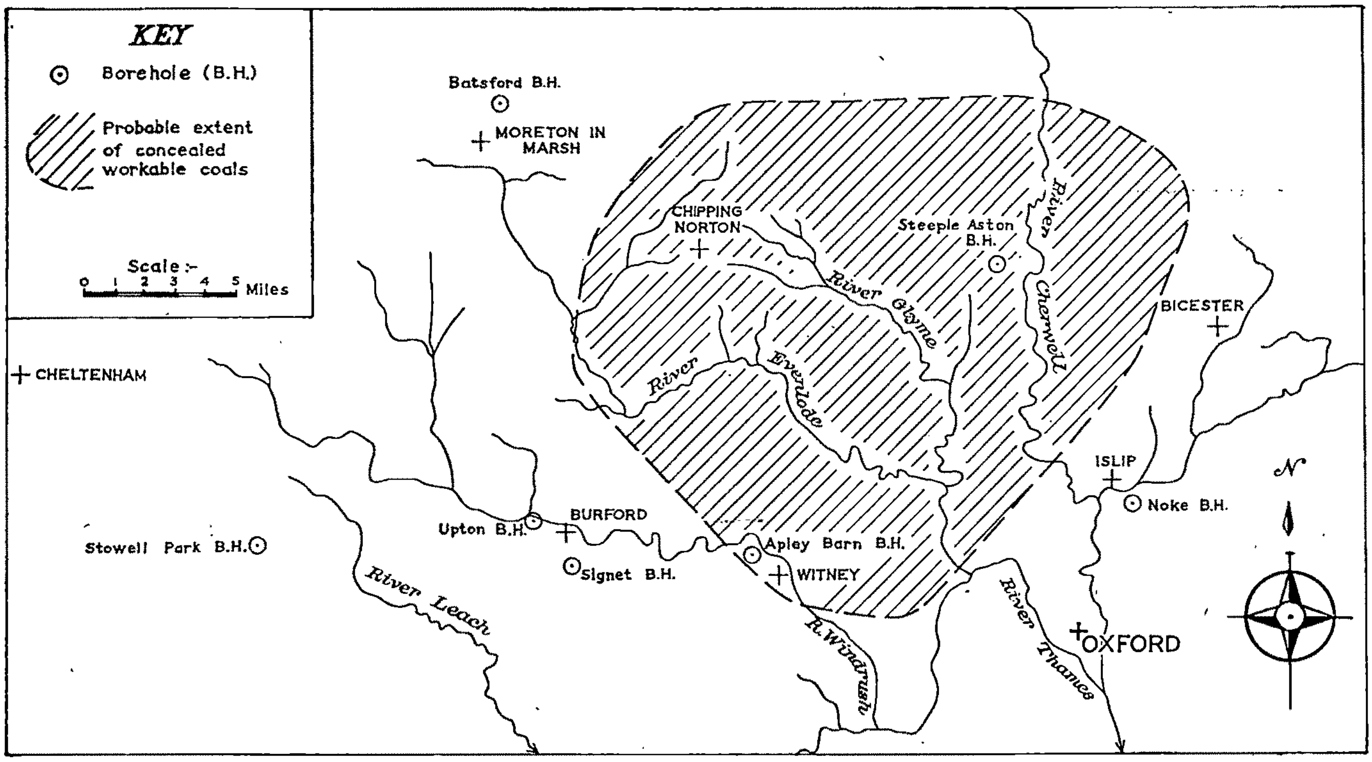

Fig. 1 Probable area of concealed workable coal in Oxfordshire.

upper part of the Pennant Group of the Forest of Dean Coalfield[2].

In the Apley Barn Borehole, the Upper Coal Measures rested unconformably on Upper Devonian sandstones, conglomerates and red and green mudstones but in the Steeple Aston Borehole a thick suite of basic intrusive rocks and agglomerates occurred beneath the Arenaceous Coal Group at 2,003 feet 6 inches (610.67 m) down to 2,545 feet 4 inches (775.82 m). Below these rocks a unique sequence of Upper Devonian marine and estuarine sediments was proved down to 3,172 feet 3 inches (966.90 m). These beds, which are yielding highly significant palynological and palaeontological results, are intruded by six thin basalt sills and the borehole was terminated in yet another basalt intrusion at 3,199 feet 3 inches (975.13 m). Natural gas was encountered in some of the sandstones of the Arenaceous Coal Group and the Devonian which was almost certainly produced by the thermal metamorphism of these carbonaceous formations. If the intrusions are of widespread lateral extent then it is possible that a small gas field may exist in the vicinity of the borehole; this would have to be proved by further drilling and pumping tests.

The probable area of concealed workable coals is shown in Fig. 1. The absolute northern limit is unknown but it almost certainly does not reach as far as Banbury, where the gravity anomaly map shows igneous or dense basement rocks at a comparatively shallow depth. Similarly it does not extend as far to the south-east as the Noke[3] Borehole (some 5 miles north-east of Oxford) where Upper Old Red Sandstone underlies Mesozoic rocks at a depth of only 380 feet (115.82 m). The north-easterly limit is very uncertain and might well extend some distance beyond Bicester. The Apley Barn and Upton[4] boreholes effectively prove the southerly and south-westerly limits of working on grounds of depth of burial. The absolute westerly limit is undetermined, but to the north-west the Batsford Borehole[5] proved 524 feet 6 inches (159.87 m) of Upper Coal Measures but no workable seams. Thus the estimated total area where workable seams may reasonably be expected to occur may be as great as 200 to 250 square miles and may contain some 6,000 million tons of coal. The apparent dip in the Upper Coal Measures in both the Apley Barn and Steeple Aston Boreholes was low (3° to 4°) and the area is probably one of simple structure. It should be emphasized, however, that the seams are thin, probably uneconomic at the present time, and that a great deal of further exploration would be necessary before a working colliery could be established in the area.

Formation of 2,3,7,8-Tetrachlorodibenzodioxin by Thermal Decomposition of Sodium 2,4,5,-Trichlorophenate

IN the course of investigating an explosion which occurred in the Coalite Company's 2,4,5-trichlorophenol plant in 1968, a white crystalline solid of high melting point and extremely high toxicity was isolated which proved to be 2,3,7,8-tetrachlorodibenzodioxin. The manufacture of 2,4,5-trichlorophenol involves the hydrolysis of 1,2,4,5-tetrachlorobenzene using methanol and caustic soda at elevated pressure or ethylene glycol and caustic soda at atmospheric pressure. The plant in which the accident occurred used the latter process.

Small scale experiments in which 1,2,4,5-tetrachlorobenzene hydrolysates were allowed to heat up to higher temperatures than the normal 180° C showed a significant exothermic reaction after residual ethylene glycol had distilled off. Hydrolysates of all isomers of trichlorobenzene and mixtures of caustic soda and ethylene glycol all had the exothermic reaction in common starting in the 230° C region and proceeding rapidly and uncontrollably to around 410° C. This exotherm, which we attributed to the decomposition of sodium 2-hydroxyethoxide ($NaOCH_2CH_2OH$), was invariably accompanied by a huge volume of white vapours. Full analyses of the evolved gases were never possible although the presence in trace amounts of ethylene oxide was established. In the course of one such exothermic reaction of a 1,2,4,5-tetrachlorobenzene, distillate was collected which contained the usual di, tri and higher ethylene glycols and a white microcrystalline solid, melting point 298°–300° C, of elemental analysis 43.93%, 1.88% H, 36.70% Cl with the residue oxygen; this was designated C8.

A small sample of C8 recrystallized from benzene was examined by spectroscopic and gas liquid chromatographic techniques. Mass spectrographic studies of pure C8 and an authentic sample of 2,3,7,8-tetrachlorodibenzodioxin showed them to have identical fragmentation patterns, and the former to have molecular weight 322. The nuclear magnetic resonance spectrum of C8 showed one singlet proton signal at $\tau = 3.7$; no response was observed in the aliphatic region of the spectrum; this is consistent with the symmetrical structure of 2,3,7,8-tetrachlorodibenzodioxin. Gas liquid chromatographic traces of authentic 2,3,7,8-tetrachlorodibenzodioxin and C8 run in precisely the same conditions gave single peaks of the same retention time. On this evidence it was concluded that purified C8 and 2,3,7,8-tetrachlorodibenzodioxin were identical and the elemental analysis quoted earlier which corresponded more closely to $C_{14}H_7Cl_4O_4$ than the required $C_{12}H_4Cl_4O_2$ reflected its relative lack of purity.

The high toxicity and chloracnogenic effects of 2,3,7,8-tetrachlorodibenzodioxin have been previously reported[1-6]; checks were therefore made on C8 using rabbits. Single oral doses of 1 or 10 μg/kg were given to the animals; the higher dose level killed them all, and the lower dose caused serious liver damage and chloracne. This demonstrates the exceptional toxicity of this material.

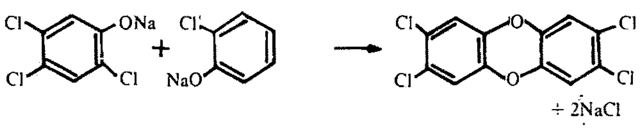

Fig. 1

The 2,3,7,8-tetrachlorodibenzodioxin (dioxin) was formed by mutual reaction of sodium 2,4,5-trichlorophenate molecules (Fig. 1) under the influence of the highly exothermic decomposition of sodium 2-hydroxyethoxide and sublimed from the reaction mixture. In preparative experiments using this method, very low yields of dioxin were isolated, chiefly because of its low tendency to sublime, but there is strong evidence of its presence in the residue after thermal decomposition. For example 218 g hydrolysate (containing 91 g of sodium 2,4,5-trichlorophenate) with a dioxin content of 17 p.p.m. was heated at 230°–260° C for 2 h, and gave a sublimate of only 6.4 mg dioxin, but the residue had a dioxin content of 1,600 p.p.m. Heating 1,2,4,5-tetrachlorobenzene hydrolysates at 180° C (normal reaction temperature) even for prolonged times gave only minimal dioxin contents.

Experiments on the thermal decomposition of hydrolysate of 1,2,3-, 1,2,4-, and 1,3,5-trichlorobenzenes (which collectively contained all six isomers of dichlorophenols), in identical conditions to those which produced C8, while undergoing exothermic reactions gave no visible or gas liquid chromatographic evidence of lower chlorinated dioxins. Distillates and residues formed in these thermal decompositions when tested for toxicity and chloracne on rabbits showed no harmful effects at all at doses as high as 1 g/kg. It is reasonable to conclude that in these conditions no lower chlorodioxins are formed.

A practical outcome of the isolation of the highly toxic dioxin was the development of a gas liquid chromatographic technique of analysis and monitoring of dioxin at all stages of 2,4,5-trichlorophenol manufacture. A revised reaction scheme minimizing the dioxin content of the product was worked out for a new 2,4,5-trichlorophenol plant which was commissioned in late 1969, and the safest possible method devised to dispose of dioxin contaminated residues. Currently produced 2,4,5-trichlorophenol contains < 1 p.p.m. dioxin.

We thank Mr R. Davies of the Huntingdon Research Centre for investigations on the rabbits.

BIOLOGICAL SCIENCES

Identification of Primate Sexual Pheromones and the Properties of Synthetic Attractants

OLFACTORY communication is now known to be important in determining the interaction between the sexes in a microsmatic higher primate, namely, the rhesus monkey[1,2]. Vaginal secretions of ovariectomized, oestrogen-treated female rhesus monkeys contain "copulins" that stimulate the mounting activity and ejaculatory behaviour of male rhesus monkeys[3]. The behavioural effects of these secretions were blocked in males made temporarily anosmic, but became apparent when olfactory acuity had been restored; they thus seem to possess the properties of olfactorily acting pheromones. We have therefore investigated the chemical nature of these sex attractants.

Behaviourally active constituents of vaginal secretions can be extracted into ether[4]. A solution prepared by washing ether extracts with N/100 sodium hydroxide, acidifying the alkaline layer and re-extracting into ether, retained behavioural activity: results which suggest that these active constituents were acidic. We report here the further fractionation of vaginal secretions by chromatography on the anion-exchanger, diethylaminoethyl (DEAE)-cellulose, and on the identification of behaviourally active constituents by gas chromatography and mass spectrometry. To confirm our results, we made a synthetic mixture of authentic compounds and tested it on ovariectomized rhesus monkeys for its capacity to attract and stimulate males.

Procedures for testing the behavioural activity of samples have been described previously[3]. Essentially, tests consisted of applying a sample directly to the sexual skin of ovariectomized, untreated female rhesus monkeys. These had been ovariectomized at least 6 months before and were unreceptive to males which generally showed little sexual activity with such females. Samples were applied to these females immediately before behavioural tests with active males, each test lasting 1 h, during which animals were observed from behind one way vision mirrors. Sixty-six tests were conducted with four pairs of animals and changes in the interactions of the pair were measured and filmed using behavioural criteria described before[5,6]. Particular attention is given here to changes in the numbers of attempts at mounting of females by males and to the changes occurring in the numbers of ejaculations. Two further ovariectomized rhesus monkeys, each receiving 10 μg oestradiol monobenzoate subcutaneously daily, were used to provide a source of secretions: these were collected twice daily by lavage with a vaginal pipette using 1 ml. distilled water and were immediately extracted into 2 ml. of diethyl ether. A pool of forty extracts was washed with 5 ml. N/100 sodium hydroxide, titrated to *p*H 7.4 and eluted through a column of DEAE-cellulose (Whatman DE-52) with 50 mM (*p*H 7.4) sodium phosphate buffer. The eluate was automatically collected into fractions which were then combined according to their elution volume relative to that of a phenolic component, detected by continuous monitoring for ultraviolet absorbance at 280 nm (Fig. 1), and now identified as *p*-hydroxyphenylpropionic acid (HPPA). Fractions were acidified, extracted into ether, and tested for behavioural activity. That corresponding to 30–50% of the elution volume of HPPA was found to be highly active (Fig. 2*A*). The number of attempts at mounting females made by the two males increased from six during twelve pre-treatment tests, when ether was applied for control purposes, to fifty-two during twelve treatment tests when the fraction was applied (χ^2 test, $P < 0.01$): there were no ejaculations during the pre-treatment period compared with twelve during treatment (χ^2 test, $P < 0.001$).

Ether extracts of the behaviourally active 30–50% fraction were further examined by analytical gas chromatography using 'Carbowax 20M'-terephthalic acid columns in Pye 104 and Perkin–Elmer F 11 gas chromatographs. The retention times of the five most volatile components, 86, 131, 152, 203 and 251 U, were compared with those of the following acids: acetic (87 U), propionic (131 U), *iso*-butyric (152 U), *n*-butyric (203 U), *iso*-valeric (251 U). A synthetic mixture of these acids co-injected with an equal volume of the natural extract showed no separation between the two mixtures. Confirmation of the identity of the five components was obtained by preparative gas chromatography and mass spectrometry. Five aliquots (2 μl. each) of the active ether extract were separately injected onto the same column fitted with a preparative attachment (10/1 effluent split). The effluent corresponding to each of the five peaks was collected individually in melting point U-tubes at −70° C: these were cut and installed in the direct insertion probe of an AEI-MS 9 mass spectrometer. The resultant mass spectra were compared with those of authentic samples obtained in the same way to avoid differences resulting from the presence of solvent or column impurities. These spectra established the identification of the five volatile constituents of the active fraction.

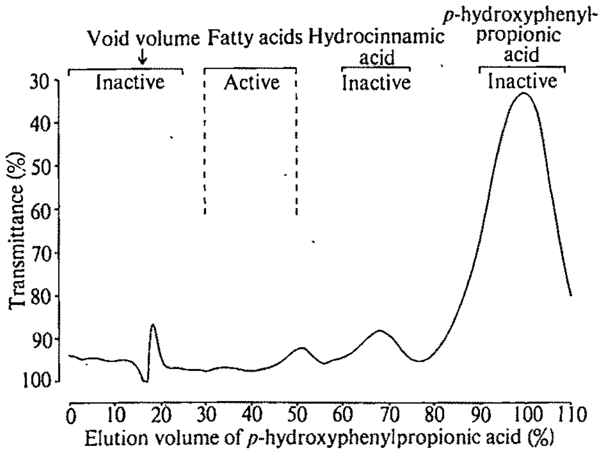

Fig. 1 Elution profile at 280 nm on DEAE-cellulose of alkaline re-extracts of vaginal secretions from ovariectomized, oestrogen-treated rhesus monkeys. The fractions were tested for behavioural activity; that containing fatty acids was found to be active, and was subjected to further analysis by gas chromatography and mass spectrometry.

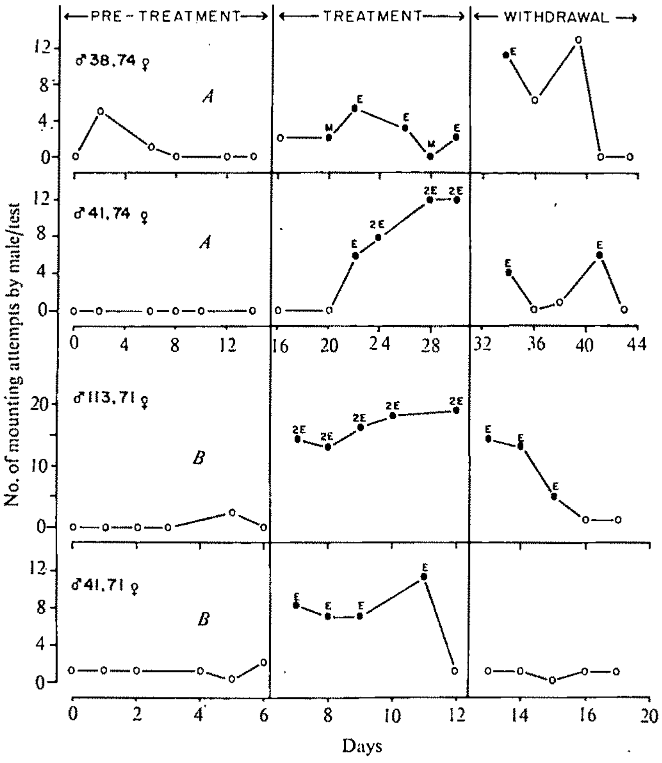

Fig. 2 Sexual stimulation of male rhesus monkeys by: *A*, the 30–50% fraction of vaginal secretions separated on a DEAE-cellulose column as indicated in Fig. 1; *B*, a synthetic mixture of the five short-chain fatty acids specified in the text.

To ascertain if the five aliphatic acids in the behaviourally active fraction were responsible for its sex attractant properties, a mixture of authentic acids was made up to match the concentrations present in a pool of twenty-four washings collected from three ovariectomized females treated with oestrogen. The synthetic mixture contained 9.2 μg acetic, 8.8 μg propionic, 4.2 μg *iso*-butyric, 12.8 μg *n*-butyric and 8.3 μg *iso*-valeric acids/ml. of ether. A 2 ml. sample of this mixture, containing about 1.5 times the acid content of a single vaginal washing, was applied to the sexual skin of each of two ovariectomized females and tested for behavioural activity (Fig. 2*B*). The number of mounting attempts made by the two males increased from eight during twelve pre-treatment tests, when ether was applied for control purposes, to 114 during ten tests when applications of the synthetic mixture were made (*t* test, $P < 0.001$): there were no ejaculations during the pre-treatment period compared with fourteen during treatment χ^2 test, $P < 0.001$). The persistence of mounting and ejaculation in some tests after withdrawing treatment was attributed to the influence of a recently rewarding sexual experience which exerted a reinforcing effect on subsequent behaviour[4].

The identification of these volatile aliphatic acids as naturally occurring constituents of vaginal secretions in the rhesus monkey, and the demonstration that a synthetic mixture of authentic acids possesses equally powerful sex attractant properties, together provide strong evidence that the attractant properties of oestrogen-stimulated vaginal secretions depend, at least in part, on their acid content. This view is strengthened by the absence of acids, or their presence in very low concentrations, in the secretions of ovariectomized, untreated females[7]. We have already established that the behavioural effects of the unfractionated, parent sections are mediated by olfaction[1], so we assume that fractions of these secretions act similarly. These findings identify and chemically characterize male sex attractants produced by a female primate, but this in no way precludes the existence of other unidentified substances with related effects. Their production by other than vaginal sources —for example, the glands of the skin—is currently being investigated.

p-Chlorophenylalanine and Copulatory Behaviour in the Male Rat

EVIDENCE has accumulated that copulatory behaviour in the female and male rat is inhibited by increased central nervous serotoninergic tone[1-4]. One approach to the study of the specificity of the antagonistic relationship between serotonin and copulatory behaviour has been selectively to increase serotonin by the combination of a monoamine oxidase inhibitor and the serotonin precursor 5-hydroxytryptophane (5-HTP). B. J. M. has shown that this treatment inhibits the copulatory response (lordosis reflex) in the female rat[4] and we have also shown[3] it to decrease the number of male rats mounting oestrous females. Analogous experiments with the catecholamine precursor dihydroxyphenylalanine (DOPA) revealed no inhibitory effect of increased catecholamine concentrations. According to the studies of Shillito[5,6] and Tagliamonte *et al.*[7], a selective decrease of serotonin by the serotonin synthesis inhibitor *p*-chlorophenylalanine[8] augmented sexual and social interaction between male rats, and in our work this agent also facilitated sexual receptivity in oestrogen-treated ovariectomized females[9]. Increased copulatory behaviour after *p*-chlorophenylalanine treatment has recently been shown in the male and female cat[10,11], although contradictory results are also available[12-14]. The purpose of the experiments described here was to study the effect of *p*-chlorophenylalanine on heterosexual mounting behaviour in castrated males, which had been given a dose of testosterone adjusted to maintain a submaximal mounting response.

The subjects were 140 male Wistar rats (350–420 g, specific pathogen free, Möllegaard, Ejby, Denmark) castrated as adults and with proven sexual experience before castration. Copulatory tests took place during the dark period of a reversed day–night cycle (11 h dimmed light, 13 h bright light). The male was allowed 5 min of adaptation in the test cage before a receptive female (spayed female treated with 50 μg of oestradiol benzoate 53 h before the test and 1 mg of progesterone 5 h before the test) was introduced. The time allowed from the introduction of the female to the first mount was restricted to 3 min. If the male mounted within 3 min the test continued for another 3 min or until ejaculation had occurred. In this account we are concerned chiefly with the readiness of the males to mount. Tests were carried out regularly once a week throughout the investigation.

Three to five weeks after castration the number of animals which mounted the receptive female had decreased to about 50%. After less than 50% of a batch of animals had mounted the female in two consecutive weekly tests, testosterone propionate was given to the whole of the batch. Treatment was once a week and the animals were tested 3 or 4 days after the hormone treatment. The dose (0.14–0.20 mg kg^{-1} given subcutaneously) was adjusted to give a submaximal response as to the number of males with mounting behaviour within the 3 min observation period. After the response rates at the weekly tests had become stable, the main experiment began.

The experimental group was given a neuropharmacological agent and a control group received a blank solution: this was our "experimental test". As a comparison, the last no-drug test—the "pre-experimental test"—was used.

DL-*p*-Chlorophenylalanine methylester HCl (PCPA), 100 mg kg^{-1}, was given intraperitoneally for 4 days and the animals were tested 6 h after the last injection. There was a significant increase in the number of animals which mounted the female and also the number of mounts performed each minute (Table 1*A*). By giving more testosterone, the response rate was increased to about 70–80% of males mounting, and the stimulatory effect of PCPA on the readiness to mount a receptive female was no longer obvious (Table 2). If the subject was retested after 0.5–1 h, however, this time with a castrated male introduced instead of a receptive female, there was a significant increase in mounting behaviour compared with animals not treated with PCPA. Previously[13] no stimulatory effect was seen on the heterosexual copulatory behaviour of intact vigorous males after PCPA treatment, but rather an effect on the mounting of intact males by intact males[5-7]. Our data indicate that the stimulatory effect of PCPA on male copulatory behaviour is only visible if the males are on a testosterone treatment which is submaximal as to activation of mounting behaviour. The fact that it was still possible to detect an effect when a male instead of a female was used as mounting partner might be a result of the fact that the male was less of an incentive as a mounting object.

To test whether the augmented mounting response could be attributable to a non-specific increase in exploratory behaviour, locomotor activity was measured by an 'Animex' activity meter (Farad Electronics, Hägersten, Stockholm). Movement of the animals across a tuned oscillator coil system results in change of the tuning which is recorded as a count. One subject at a time was placed in the apparatus. Each recording lasted 10 min and was carried out 0.5–1 h after the copulation test (Table 1*A*, 1–2). PCPA treatment decreased spontaneous locomotor activity. To rule out the possibility that this result was caused by fatigue after the test, another batch of six plus six animals was tested in the 'Animex' after the same drug treatment but without a copulation test and at the time at which the copulation test would have been performed. The result was very similar (Table 1*A*, 3–4). Thus, PCPA increased the number of males mounting and the number of mounts per minute, although the animals became sluggish in the locomotor test. This emphasizes the specificity of the augmenting effect of PCPA on the readiness of the male to mount a receptive female.

The effect of PCPA on copulatory behaviour was also investigated in twenty-six adrenalectomized males. All received

0.9% NaCl in their water bottles and once a week dexamethasone, 0.5 mg per animal, was given subcutaneously. Experimental animals were given PCPA intraperitoneally, 100 mg kg^{-1} on the first day and 50 mg kg^{-1} each day for another 3 consecutive days, and they were tested 6 h after the last injection. Compared with the pre-experimental test values and the saline-treated controls there was an obvious increase in the mounting performance of subjects treated with PCPA (Table 1*B*). This stimulatory effect on the readiness to mount a receptive female in castrated and adrenalectomized males rules out the possibility that PCPA increases the mounting rate by stimulating endogenous testosterone production. The number of mounts per minute (pre-experimental test) was less than in rats not adrenalectomized, probably because in spite of the dexamethasone treatment the animals became less alert after adrenalectomy. The limited number of subjects (three) which mounted both in the pre-experimental and experimental test makes it difficult to say whether there is a true increase in mounts per minute.

It has been demonstrated[3] that the general increase of monoamine concentrations achieved by the monoamine oxidase inhibitor pargyline (40 mg kg^{-1}, given intraperitoneally) significantly inhibited mounting behaviour in males. This is confirmed in this study (Table 3*A*). We investigated the possible prevention of this inhibition by decreased biosynthesis of serotonin caused by PCPA. When the animals were pretreated with PCPA, 4×100 mg kg^{-1}, given intraperitoneally, the inhibitory effect of pargyline on the mounting behaviour was not obtained (Table 3*B*) (see *Note added in proof*). A comparison of the data in the experimental test with the results of the pre-experimental trial reveals that there was still an evident increase in the percentage of animals mounting. The increase in mounting was about the same as if pargyline had not been given (compare Table 1*A*). In contrast to animals treated only with PCPA, however, there was no significant change in the number of mounts per minute. The inhibitory effect of PCPA on serotonin biosynthesis (tryptophane hydroxylase inhibition) does not involve the step from the precursor amino-acid 5-HTP to serotonin. Thus, by treating with 5-HTP it is possible to increase serotonin concentrations although PCPA has been given. DL-5-HTP was injected 30 min before the mating test in an otherwise analogous PCPA plus pargyline experiment, which gave a clearcut inhibitory effect on the copulatory behaviour (Table 3*B*, 2). Overt behaviour was no more affected in these animals than in those which had PCPA alone.

These data suggest that PCPA in the male rat increases the hormone-activated copulatory response. This effect is probably related to the ability of PCPA to decrease the serotoninergic tone, although the possibility that PCPA interacts with further biochemical events which would contribute to its effect on copulatory behaviour cannot be excluded. In the female rat, the results of similar experiments led to the hypothesis that there are serotoninergic pathways mediating inhibition of copulatory behaviour[1,2,4,9,15]. It has been suggested that decreased serotoninergic activity would remove this inhibition and thereby enhance the hormone-activated copulatory response. This hypothesis can be extended to male copulatory behaviour.

One may ask whether this inhibitory system is restricted to the sex-specific copulatory behaviour pattern or if female behaviour in the male and male behaviour in the female is under the same serotoninergic control. Previous data suggest the latter: decreased monoamine concentrations achieved by amine depletors (reserpine and tetrabenazine) facilitate female copulatory behaviour (lordosis response) in oestrogen-treated males castrated as adults[16]. The specificity of serotonin in this respect needs further investigation, however.

We thank Miss Ann-Kristin Söderlund for technical assistance. Oestradiol benzoate and progesterone were donated by Pharmacia, Uppsala, Sweden; testosterone propionate by

p-Chlorophenylalanine facilitates Copulatory Behaviour in Male Rats

IT has been proposed that the inhibition of male copulatory patterns by anterior portions of the nervous system[1] is mediated by brain monoamines[2–4], for reserpine facilitates certain aspects of the male pattern in rats[3–5] although monoamine oxidase inhibitors retard copulatory behaviour (D. A. D., H. N. Davis and P. E. Jansen, results submitted for publication). Meyerson has proposed[6] that an analogous mechanism may control female oestrous behaviour in rats.

These data suggest that *p*-chlorophenylalanine (PCPA), which depletes brain serotonin[7], should facilitate male copulatory behaviour as it does female oestrous behaviour[8]. Evidence that this drug facilitates mounting behaviour in male rats[2,9–12] supports this hypothesis. But another report[13] indicates that the species typical copulatory pattern of male rats is not affected by PCPA. We have now demonstrated that PCPA can substantially facilitate the normal pattern of heterosexual behaviour in the male rat.

Twenty-three male Long–Evans rats 95 days old were pretested—each was handled, followed by two successful tests of copulatory behaviour. Twenty-eight females of the same age and strain served as partners. Tests were conducted in 'Plexiglas' arenas 76–86 cm in diameter and 61–66 cm high.

Each male received three experimental tests of copulatory behaviour at intervals of 4 weeks. Tests followed administration of isotonic saline, 50 mg kg^{-1} or 100 mg kg^{-1}, of a saline suspension of DL-*p*-chlorophenylalanine (*p*H 1.8). Injections were given intraperitoneally on four successive nights between midnight and 0100 h and tests were initiated on the day after the fourth injection at 0300 h—5 h after the beginning of the dark phase of the light–dark cycle. Subgroups were tested in each of the six possible running orders in a balanced design.

The tests began with the introduction of a receptive female into the test arena 5 min after the introduction of the male, and were terminated after the first intromission following the third ejaculation by the male. Females were brought into behavioural oestrus with intramuscular injections of 0.1 mg of oestradiol benzoate 3 days before testing and 1.0 mg of progesterone approximately 3 h before testing. Only receptive females were used.

Copulatory behaviour in rats consists of bouts or series of mounts (without intromission) and vaginal intromissions, with each complete series terminated by an ejaculation. We considered the following standard measures: mount latency (ML)—the period from the introduction of the female to the first mount; intromission latency (IL)—the period until the first intromission; ejaculation latency (EL)—the period from the first intromission of a series to ejaculation; intromission frequency (IF)—the number of intromissions in a series; mount frequency (MF)—the number of mounts in a series; mean inter-intromission interval (MIII)—the mean interval separating the intromissions of a series; and post-ejaculatory interval (PEI)—latency from ejaculation to the next intromission. Individual series are designated by a hyphen and the appropriate number (for example, IF-3).

We used multivariate analyses of variance with repeated measures[14] on our data. There was a significant overall effect of drug condition across series on all five measures characterizing series (EL, MIII, PEI, IF, MF). The mean scores and

significance levels for all the measures for individual series are presented in Table 1. It is evident that PCPA substantially facilitated most aspects of the copulatory pattern. The means of all measures for all series have consistent differences indicative of this facilitation. Many of these differences were significant at the 0.05 level or better. In several cases, changes in group means in the drug treatments were accompanied by changes in group variances; in general, the drug treatments produced decreases in variances, although there were exceptions to this trend. Ejaculations were usually attained sooner, and after fewer mounts and intromissions, than after saline administrations, and post-ejaculatory refractory periods were shorter. Both dose levels facilitated the behaviour at least to some extent, but there were more significant differences after administration of the higher dose.

The demonstration of a facilitation effect of PCPA on male rat heterosexual copulatory activity is consistent with its facilitation of mounting behaviour[2,9–12]. The effects of PCPA on copulatory behaviour of male cats are unclear[15,16]. Our data are inconsistent with a study[13] in which there was no effect of PCPA on heterosexual copulation in male rats. Differences between the two experiments which might account for our positive results include: our use of the reported[2,12] optimal injection-test interval; our use of a larger number of subjects; our confinement of tests to a part of the photoperiod in which copulatory behaviour is relatively fast and variability relatively low[17]; our use of a balanced testing order with different subjects receiving treatment in all possible orders; and differences in the form and mode of injection of PCPA.

These data, together with others from our laboratory[3,4], are consistent with the hypothesis that brain monoamines, and particularly serotonin, inhibit male copulatory behaviour.

This research was supported by a grant from the National Science Foundation. We thank P. L. Perlman of the Schering Corporation for hormones, Dr N. Belcher of Pfizer and Co. for PCPA and Dr C. Becker of the University of Florida for preparing the suspension.

Mate-seeking by Female *Amblyomma maculatum* (Acarina: Ixodidae) on a Bovine

Little information is available concerning the attraction between sexes of ticks, and the literature contains no reports of sex pheromones in these arachnids. In some tick species the males are known to seek the attached females[1–4], though male bont ticks, *Amblyomma hebraeum* Koch, in Africa probably attract females[5]. When, however, I investigated the mating behaviour of the Gulf Coast tick, *Amblyomma maculatum* Koch, on bovines restrained inside environmentally controlled stalls (24 ± 3° C; 70 ± 7% relative humidity; 12 h photophase: 12 h scotophase per 24 h photocycle), I found that the females were attracted to the males.

In preliminary tests, female *A. maculatum* (AM) did not attach to a bovine, either alone, or in the presence of males of another species in the same genus (*Amblyomma americanum* (L.) (AA)). This effect is unusual because females of other tick species do attach to hosts in the absence of males[6–8].

Therefore, in three replicates, stanchioned bovines were fitted with mating chambers (sleeves)[9] and infested with ten ticks of each sex in the following combinations on the indicated day (counting day 1 as the time of first infestation): (1) AA males on day 1 and AM females on day 6; (2) AA males and AM females both on day 1; (3) AM females on day 1; (4) AM males on day 1 and AM females on day 6; (5) AM males and AM females both on day 1.

After the scheduled infestation was complete, the sleeves were inspected every 24 h for 8 days (counting from the day of infestation with females), and the number of attached AM females was recorded. Attachment of all ten females occurred only in sleeves that contained the AM males (treatments 4 and 5; Table 1), and 100% attachment of females occurred 5 days sooner in sleeves that contained already-attached AM males (treatment 4) than in sleeves that received the AM females and AM males at the same time (treatment 5). Apparently the males must feed for several days before most females will attach. Few females introduced into sleeves without males were stimulated to attach, and those that did attach remained no longer than 24 or 48 h. Rates of attachment of females in sleeves containing AA males were intermediate between those of females in sleeves with males of the same species and those of females in sleeves without males. Possibly the presence *per se* of the males or an interspecific pheromone induced moderate attachment of AM females in sleeves with AA males.

Table 1 Rates of Attachment to Bovines of AM ♀♀ placed Inside Sleeves Alone or with One of Four Groups of ♂♂

5	At the same time as AM ♂♂	1	0	1	3	6	8	10	10	10*
		2	2	3	10	9	6	6	10	10*
		3	0	0	5	9	10	10	10	10

Each sleeve contained ten ticks of each sex.

* First mating observed.

† First detachment of mated, engorged females observed.

The females that attached in sleeves containing attached AM males (treatment 5) were mated beginning 2 or 3 days after the females were introduced, and detached when replete. Females introduced into sleeves at the same time as AM males (treatment 4), however, were not mated until 8 days post-infestation, because the completion of spermatogenesis by many male ixodid species does not take place until after they feed[1]. Females released into sleeves containing conspecific males engorged partially were mated by the males, and eventually detached when replete. Females that attached in sleeves by themselves (treatment 3) or in sleeves with AA males (treatments 1 and 2) imbibed no discernible amounts of blood, and cross-mating did not occur between AA males and AM females.

Because each AM female that was introduced into a sleeve containing attached AM males actively sought the site of the male and attached immediately adjacent to it, the behaviour of AM females in seeking AM males was studied further in another test in which the two sexes were not confined in close proximity. The methods were similar to those used in a study of the migration of AA males to AA females on bovines[4] except that the AM females, not the males, were marked and released.

Each AM female was marked on the dorsum with 1 µl. of saturated acetone solutions of fluorescent powders (Series A pigments; Day-Glo Color Division, Switzer Bros., Inc., Cleveland, Ohio). Four days before the marked females were to be released on stanchioned bovines, the animals were infested with seventy-five AM males which were confined on an area of the upper shoulder by the stockinette-sleeve technique[4]. After 4 days, the sleeve was removed, and twenty-five females were released onto each of three areas (the hocks of one front and one hind leg, and the belly of the animal) on the sides of the animals opposite the sides on which the males were attached. Each group of twenty-five females was marked with a different colour for each site of release. Many females did not cling firmly to the hair of the animals and fell to the floor of the stall immediately after release and were subsequently lost.

At 24 h after release, the marked females were located on the animals with a portable ultraviolet lamp, and the site of attachment of each tick was recorded on a diagram of the animal. For a further 11 days, the cattle were inspected daily for paired adult ticks. Females found within 1 cm of a male were removed, examined under the ultraviolet lamp, and then discarded. I was therefore able to determine how long the females were on the hosts before they located the males. The test was replicated six times.

By 24 h after release, eighty of the ninety-two detected females had preferred to attach within 1 cm of males rather than attach at any other site on the animals' bodies; the second most preferred site of attachment (eight out of ninety-two) was the ears, even though no males were present in them. Thus, most females located males within 24 h regardless of the site of initial infestation (the last female took 10 days to reach the males). Of a total of 450 marked females originally released on the animals, 111 (25%) were paired with males when collected.

I thank R. O. Drummond and C. C. Dawkins for their assistance.

Systemic Action of an Insect Feeding Deterrent

Many phytophagous insects are restricted in host range because of the presence of naturally occurring distasteful chemical substances in otherwise acceptable plants[1,2]. In the search for possible substitutes for toxic pesticides, however, comparatively little attention has been directed towards the application of non-toxic antifeeding compounds or rejectants as a means of deterring insects from attacking crops. To be of practical value, a rejectant should not only be persistent but also absorbed and translocated to the growing points of treated plants. Otherwise the new plant growth developing after treatment, being uncontaminated, will be selectively attacked while the older treated leaves remain distasteful.

The neem tree *Azadirachta indica* has many uses, one of which is that a suspension of crushed seeds or leaves will deter some insect species from feeding when applied directly to plant foliage or stored products. A compound which is a potent rejectant for the desert locust, *Schistocerca gregaria* Forsk[3,4], has been isolated from seeds and termed azadirachtin[5] though its structure has yet to be elucidated. We have now obtained results which show that azadirachtin, and possibly other substances present in neem extracts, can be absorbed by the roots and translocated within bean plants to act as a systemic rejectant.

Three products were tested against *Schistocerca* adults. These were (1) azadirachtin, the pure chemical; (2) an alcoholic concentrate, refined from a 95% ethanol extract of neem seed, containing 3.8% by weight of the seed; and (3) an aqueous suspension prepared by grinding seed kernels in water until the material passed through a 100-mesh sieve.

These products were diluted with water containing 0.05% 'Teepol' and applied in a range of seven concentrations to the soil around young bean plants at the six to eight leaf stage. The bean plants were transplanted singly to plastic cups containing 150 g of a soil consisting of a sieved and sterilized mixture of 3 parts loam, 2 parts sand and 1 part peat, and the different treatments were applied in 10 ml. as part of the first watering. The efficacy and persistence of the treatments were assayed by placing the treated plants, together with controls, randomly in a $0.31\ \mathrm{m}^3$ cage with 200 adult desert locusts which had been starved for 8–10 h. After 12 h of exposure to the hungry locusts, the damage suffered by each plant was assessed using a visual ranking index system. The same treated plants plus fresh controls were exposed in this way to starved locusts for 12 h after 1.5, 4, 7, 15, 21 and 25 days. The experiment was repeated three times using three replicates of each treatment and controls on each occasion. The locusts were still hungry at the end of each exposure and were ready to attack fresh control plants.

Plant damage was assessed by a ranking index: 0, no feeding; 1, very slight nibbling, apical bud intact; 2, leaves partly eaten, some damage to apical bud; 3, apical buds and 1/3 of plant eaten; 4, a few lower buds remaining on stem only; 5, all the buds and most or all of the plant eaten. Treatments are expressed as parts per million of dry soil.

The results obtained shortly after treatment and after 15 days are given in Table 1. After 25 days the plants grown in the most heavily treated soil (10, 100, 1,000 p.p.m. of azadirachtin, alcoholic and aqueous preparations respectively) were still only slightly damaged by the hungry locusts.

Similar results have been obtained using older established plants of both tall and dwarf varieties, up to the fruiting stage. As soil composition is known to have an important bearing on the systemic uptake of chemicals by plants, experiments have been carried out with five different types of soils. The results indicate that high organic content and alkalinity in soils reduce the systemic anti-feeding activities of azadirachtin and the two crude neem preparations.

In other trials, bean seedlings grown from seeds soaked for 24 h in 0.01, 0.1 and 1% solutions of azadirachtin, alcohol extract and kernel water extract, respectively, were protected against damage by *Schistocerca* adults for one week after germination in cage feeding tests.

Plant nematodes of the genus *Pratylenchus* are also deterred by seedling treatments. When barley seedlings were dipped in a 1% aqueous suspension of crushed neem kernels for 2 h, then grown in a naturally infested soil for ten days, there was a decrease (>50%) in the number of nematodes invading the developing root system. Further experiments are in progress to establish whether active compounds other than azadirachtin are present in neem extracts, using several species of test insect.

We thank Dr E. D. Morgan for azadirachtin and Dr R. Skrentny for soil samples and useful advice. J. S. G. thanks the Food and Agriculture Organization for a research fellowship and Professor T. R. E. Southwood and Dr P. T. Haskell for research facilities.

HL-A Antigens on Human Trophoblast Cells

IN an outbred population, the placenta is essentially an allograft and many hypotheses have been put forward to explain why it is not rejected by the mother during pregnancy. One possibility is that placental tissue is devoid of transplantation antigens or these antigens are prevented from being expressed.

In mice, transplantation antigens are present on trophoblast cells, but this effect is masked by a coating of inert sialomucin material[1,2]. There is only circumstantial evidence[3], however, that an analogous situation pertains in humans. By the use of monolayer cultures of human trophoblast cells, we have been able to show in cytotoxicity *in vitro* tests that HL-A antigens are present.

Cultures of trophoblast and foetal skin cells were obtained as before[4]: cells were removed with 0.1% trypsin, and resuspended in Hanks solution to a concentration of 1×10^6 cells/ml.

Cytotoxic tests were performed on siliconed Clay–Adams ceramic ring slides using 0.025 ml. unit volumes. Cells were tested against: serum of the mother from whom the placenta was obtained; a multispecific anti-HL-A serum (Burke) which gives a strong cytotoxic reaction with the lymphocytes of more than 70% of Caucasian populations; a monospecific anti-HL-A2 serum (Wolfe).

Controls were set up by incubating the cells with: serum from a group AB rhesus positive nulliparous woman (Mar-

chand) who has had no blood transfusions; Hanks only; Hanks and complement; the multispecific anti-HL-A serum without the addition of complement.

The mixtures were incubated at 37° C for 1 h in a moist container. Each test was then stained with 0.025 ml. of 0.4% trypan blue and read with a phase contrast microscope.

Both serum Burke and serum Wolfe were derived from group A rhesus positive individuals. After testing against a 'Selectogen' red cell panel, natural anti-B antibody was found in both sera but there was no evidence of antibody towards any of the following red cell antigens: rhesus C.D.E. $\bar{c}$.e.f.c.^{w}, Kell, Duffy, Kidd, Lewis, MNS, P, Lutheran, Vell, and Xg^{a}.

Trophoblast cells from four different placentae (T9, T13, T15, T16) were used. In one of these (T13), blood groups of both parents were ascertained to be group O Rhesus positive. The placenta in this case would therefore also be group O. This mother had had two previous pregnancies. The three other mothers were primigravidae. Corresponding cultures of foetal skin cells (S9, S13, S15) were also used.

The tests were scored according to the method described by Joysey[5] as shown in Table 1.

Both trophoblast and foetal skin cells reacted strongly with the multispecific anti-HL-A serum Burke, the cytotoxic activity being complement dependent (Table 2). The monospecific anti-HL-A2 serum Wolfe was cytotoxic to one out of three trophoblasts tested. None of the maternal sera had any cytotoxic activity towards their respective trophoblast or foetal skin cells.

Currie and Bagshawe[6] demonstrated that maternal as well as allogeneic lymphocytes had a cytotoxic effect on human trophoblast cells and concluded that trophoblast must have antigenic groupings foreign to the mother. Hulka *et al.*[7] found that fluorescein-labelled serum globulin obtained from post-partum women would localize in placental tissue. These experiments provide evidence for the existence of antigens on human trophoblast cells, but do not indicate whether these are HL-A determinants.

Van Rood[8] reported that serum containing anti-leucocyte antibodies was absorbed by placental tissue but Seigler and Metzgar[9] were unable to confirm the presence of HL-A antigens on whole trophoblast.

The results of our experiment have shown that a serum containing strong multispecific anti-leucocyte antibody has cytotoxic activity towards human trophoblast cells *in vitro*, and it seems likely that this activity is directed against HL-A determinants. Incompatibility due to ABO groups can be definitely excluded in one case where both parents are group O. Furthermore, both serum Burke and serum Wolfe were found to possess natural anti-B only: no antibodies against other red cell antigens could be demonstrated. The monospecific anti-HL-A2 serum Wolfe was cytotoxic to one out of three trophoblasts tested, the frequency of the HL-A2 phenotype being about 49% in the Cambridge panel.

The finding of HL-A antigens on trophoblast cells *in vitro* does not nullify the concept that these determinants may be masked *in vivo*. There have been numerous reports on the presence of a covering layer around human trophoblast cells which may fulfil this function[10-13].

In some cases, however, foeto-maternal immunization certainly occurs as indicated by the presence of anti-leucocyte antibodies in the serum of multiparous women[14,15]. It seems likely that the trophoblast may at least partly be the source of the antigenic stimulation especially as these cells are widely deported in the maternal circulation during human pregnancy[16,17]. There is a positive correlation between maternal sensitization and parity[18]. In our series, there was no demonstrable activity of maternal sera towards their respective trophoblast and foetal skin cells.

We thank the US National Institutes of Health for serum Burke. The work is supported by a grant from the Cancer Research Campaign (Y. W. L. and R. B.) and the Medical Research Council (V. C. J.).

Transplantation of Radiation-induced Canine Myelomonocytic Leukaemia

An important variant of leukaemia in man is the myelomonocytic form[1], the exact nature of which is still unclear, for the only available model for studies of this disease is the mouse[2]. We have developed a canine model which shows promise for studies of certain aspects of the pathogenesis of myelomonocytic leukaemia (MML) as related to changes that develop in a single animal. Because dogs live longer and are larger than mice, they are well suited to serial samplings of blood, bone marrow and other tissues, facilitating dynamic studies of changes in the haematopoietic system occurring with time.

Beagles continuously exposed to high ^{90}Sr concentrations developed a myeloproliferative syndrome (MPS)[3]. Several further cases of MPS were observed subsequently, including two of myelomonocytic leukaemia, and studies were undertaken to develop a canine model to aid studies of the aetiology, pathogenesis, diagnosis and possible control of the disease. This report concerns the transplantation of cells from one of the dogs with MML; similar studies utilizing cells from the other case produced comparable results.

The donor dog (D50F52), fed ^{90}Sr daily from birth, had accumulated about 5,000 rad of β-radiation to the bone marrow during her life. The diagnosis of MML (made when the dog was about 5 yr old) was based on haematological changes and confirmed by terminal pathological findings. There was a persistent significant increase in peripheral white blood cell numbers, especially granulocytes (including occasional blast forms) and monocytes. There was also an extreme increase in the percentage of granulocytes relative to other cell types in all samples of bone marrow examined (Table 1). Approximately 30% of the granulocytes in the terminal marrow samples were primitive, often atypical blast forms. Terminal lesions consisted of extensive invasion of haematopoietic organs (bone marrow, liver, spleen and lymph nodes), often with complete obliteration of the normal structure. In all the organs except the spleen, the tumour infiltrates appeared as fleshy green masses (chloroma). Most other organs and tissues contained focal accumulations of tumour cells.

Primary transplantation was accomplished with bone marrow cell preparations. Subsequent transplantations were done with cells from solid tumours or tumour ascites. The number of viable cells used in the inoculum varied from 1×10^7 to 2×10^8 cells ml.$^{-1}$. The pregnant beagles used as recipients were not related to the donor dogs. Transplantation was effected by performing a laparotomy at 46–53 days of gestation and inoculating the foetuses intraperitoneally through the uterine wall[4]. Except in passage 5, at least one foetus in each litter served as a control and was inoculated with a radionuclide marker only, for identification[4].

Animals were usually killed about a week after enlarged lymph nodes or solid tumours became evident and haematologic abnormalities were observed, which occurred 8–71 days after birth (Fig. 1).

Lesions observed in all five passages closely resembled those in the original donor dog, but were more pronounced. The population of neoplastic cells in the recipients consistently had more primitive cell types than the donor population. A further prominent feature was the occurrence, in all recipients, of large retroperitoneal masses of chloromatous tumour tissue in the sublumbar region, comprising up to 10% of the host's body weight. Peripheral blood, serum lysozyme and bone marrow values for the donor and one passage 3 recipient which manifested a severe case of MML, are presented in Table 1. All control pups had normal haemograms, and no lesions were seen in the nine control pups that were killed.

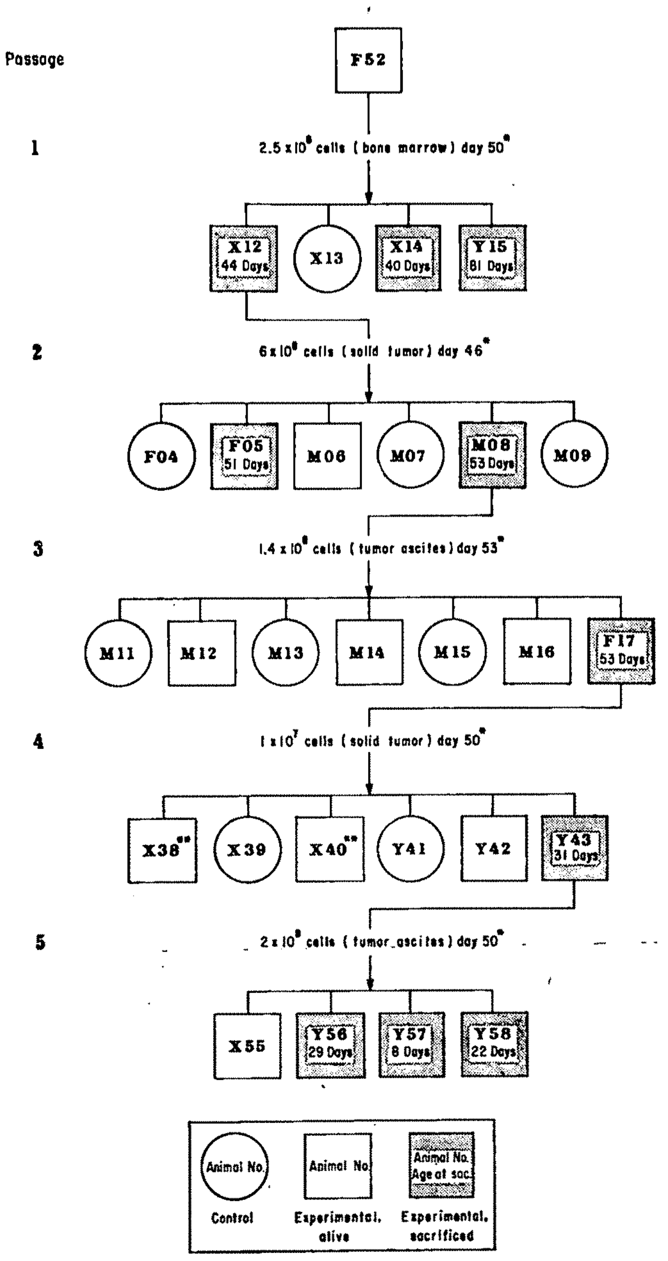

Fig. 1 Transplantation of myelomonocytic leukaemia. *, Day of gestation inoculated; **, died at birth.

Serum lysozyme concentrations, assayed by the method of Osserman and Lawlor[5], were high in the primary donor and in all recipients that developed MML, whereas lysozyme was not detected in pups that did not manifest the disease (Table 1). Increased lysozyme concentrations, primarily in urine, are found in cases of human MML, which is considered to be of value in diagnosis[5]. Electron microscopic examination of tumour tissues has not revealed any virus particles. Further work is in progress to determine the possibility of a viral aetiology for the disease.

Chromosome analysis was performed on direct preparations of bone marrow, of peripheral and mesenteric lymph nodes

Table 1 Terminal Values for Peripheral Blood, Serum Lysozyme and Bone Marrow in Donor Dog and One Recipient with a Marked Case of Myelomonocytic Leukaemia

† Promyelocytes, myelocytes, metamyelocytes, and bands.

‡ Data are presented as percentage of granulocytes rather than of total cells because few cells were seen other than granulocytes, as evident from the M/E ratio.

§ Unclassified cells consist of atypical blast cells and abnormal cells with the morphological characteristics of both granulocytic and monocytic elements.

and of solid and ascitic tumour material. Cytogenetic evaluation of the recipient puppies, by analysis of the males' sex chromosomes, showed conclusively that the tumour tissues consisted of the original female donor cells. Most of the cells examined from all the recipient puppies contained a very small, abnormal, acrocentric autosome which may be a disease-specific marker comparable with the Philadelphia chromosome that is characteristic of chronic granulocytic leukaemia in man.

To sum up, we have demonstrated, by the transplantation of malignant cells, the feasibility of using the dog as a model for the study of myelogenous leukaemia.

This work was supported in part by the US Atomic Energy Commission, in part by an NIH health sciences advancement award and in part by the National Cancer Institute. We thank S. Jean Galligan, Dr Gary Colgrove and Boyd Harrold for technical assistance, Robert Davis for excellent animal care, Ellen K. Haro for editorial assistance and Dr Leo K. Bustad for help and encouragement.

Persistent Corpora Lutea of Mice in a Cold Environment

IF laboratory mice, *Mus musculus*, are bred in permanently mated pairs in an environment kept at −3° C, their litters are usually smaller at birth than those of controls at 21° C[1]. Cold adaptation is also accompanied by differences in the relative weights of many organs and tissues[2-4]. In particular, the gonads, at least of unmated mice, tend to be lighter in a cold environment.

Smaller litters in a cold environment could be due to a lower ovulation rate or to higher losses of embryos before or after implantation. During an investigation of this and allied questions, we have made an apparently novel observation on the ovaries of cold-adapted mice. The laboratory mice were of several types, mated in separate pairs at the age of 5 weeks and allowed to rear their first litters. The males were removed shortly before the birth of the second litters, which were killed within 24 h of parturition. The males were then replaced, and the females watched for the appearance of a vaginal plug. Fifteen days after a plug was recorded, that is, on the sixteenth day of gestation, each female was killed and dissected. The ovaries were quickly removed, cleaned, weighed to the nearest 0.1 mg, fixed, serially sectioned and stained; the corpora lutea were then counted. The number of foetuses and abnormal implantations was also recorded. Some wild house mice were studied[5]: they were similarly treated, except that the males were not removed and the females were killed when visibly in late pregnancy.

The first anomalous finding was that the ovaries of the cold-adapted, pregnant mice were heavier than those of the controls. Table 1 illustrates this from mice of strain A2G/Tb, for which we also have weights of the ovaries of virgin mice at both temperatures; the ovaries of the virgins, unlike those of the pregnant females, were lighter at −3° C. The discrepancy in ovarian weights in pregnancy was due to a difference in the number of corpora lutea in the two temperatures. Table 2

gives figures for three classes of cold-adapted mice of a mixed, outbred stock. Mice which had been transferred to the cold environment as young adults before mating (21→−3° C), and those of the first generation reared at −3° C, had about 80% more corpora lutea than the controls. Mice of the same origin after many generations in the cold environment had about 42% more corpora lutea. Table 2 also shows that the number of viable foetuses was not correspondingly higher in the cold.

The effect of cold on the ovary was not a peculiarity of one type of mouse. Table 3 gives the figures for corpora lutea of mice of two inbred strains, A2G/Tb and C57BL/Tb, the F_1 generation produced by crossing them, and of wild house mice. All showed a similar effect of cold. The findings from the mixed stock (Table 2) and from strain A2G/Tb show that the effect on the ovary of transfer to −3° C at mating was the same as that of being reared (first generation) in the cold. All differences between temperatures in number of corpora lutea are statistically significant ($P<0.01$; Student's t). The wild mice, unlike the laboratory mice, also had larger litters in the cold environment ($P<0.05$).

The number of corpora lutea is usually regarded as a reliable index of the number of ova shed at the most recent ovulation. If it were so for our laboratory mice, we should have to assume exceptionally high ovulation rates in the cold environment, and corresponding losses before implantation. To test this, more pairs of the mixed stock were transferred to −3° C; pairs from the same litters were also mated at 21° C. When a vaginal plug indicated the beginning of the third pregnancy, the female was killed. The ovaries and fallopian tubes were removed, fixed and stained, and the eggs shed at that ovulation were counted. The mean number of ova per tube from nine females at 21° C was 5.6±0.5; the corresponding figure for six females at −3° C was 5.7±0.7. Hence the excess of corpora lutea at −3° C does not represent a raised ovulation rate in these mice. A methodological conclusion follows: the number of corpora lutea, at least in a mouse ovary, should not be assumed always to correspond to the effective ovulation rate. This applies especially in unusual environments.

In the eleven classes of laboratory mice the mean number of abnormal conceptions ranged from 0.87 to 2.69. The wild mice had almost none. Evidently, therefore, losses after implantation were few. There was also little or no effect of cold on the litter sizes of the laboratory mice (that is, number of normal foetuses at 16 days). This differs from previous findings[1] because the mice of the present study were never rearing a litter of sucklings during gestation, as were some of those studied in earlier work.

In experimental work on the cold-adaptation of mammals, exposure to cold is rarely longer than a few weeks, and effects on reproduction have usually been neglected. Attention has been concentrated on the changes which take place while an isolated small laboratory mammal is adjusting to a sudden lowering of environmental temperature[3]. In contrast, our mice at −3° C were presumably in metabolic and hormonal equilibrium. Nevertheless, this probably entailed pituitary and adrenal cortical activity above that at 21° C. Adrenal weights are given in Table 4; except the F_1 mice, which had heavy adrenals even in the warm environment, all classes at −3° C had heavier adrenals than at 21° C.

The large numbers of corpora lutea in the cold were probably due to persistence of the corpora lutea from a previous ovulation, resulting from the altered endocrine activity. This requires further study. So does the larger litter size of wild mice at −3° C. If these phenomena regularly accompany the cold-adaptation of other mammals, the question arises whether they occur also in other adverse conditions, such as exceptional crowding. It would be interesting to know more about the corpora lutea of species which, in their natural environment, continue to reproduce in varying conditions of climate, feeding and other environmental features.

Molecular Pathology of Human Haemoglobin: Stereochemical Interpretation of Abnormal Oxygen Affinities

WHEN the atomic model of oxyhaemoglobin had just been completed, we showed that the haemoglobin molecule is insensitive to replacements of most amino-acid residues on its surface but extremely sensitive to quite small alterations of internal non-polar contacts. And replacements near the haems and at the contacts between α and β subunits affect the respiratory function[1].

Many amino-acid substitutions in abnormal haemoglobins produce clinical symptoms by altering the oxygen affinity. Now that the atomic structures of both deoxy and oxyhaemoglobin are known[2,3] and a cooperative mechanism has been proposed[4], we can try to interpret these abnormal oxygen affinities in stereochemical terms. In the first instance, the oxygen affinity depends on the conformation of the globin pocket surrounding the haem group and on residues known to be involved in the Bohr effect or the binding of 2,3-diphosphoglycerate. But in other cases of abnormal oxygen affinity the substituted residues are far removed from any of the binding sites for either oxygen, hydrogen ions or 2,3-diphosphoglycerate. We have found that several of these substitutions alter the oxygen affinity by their effect on the allosteric equilibrium between either the two alternative tertiary structures of the individual subunits or the two alternative quaternary structures of the haemoglobin tetramer.

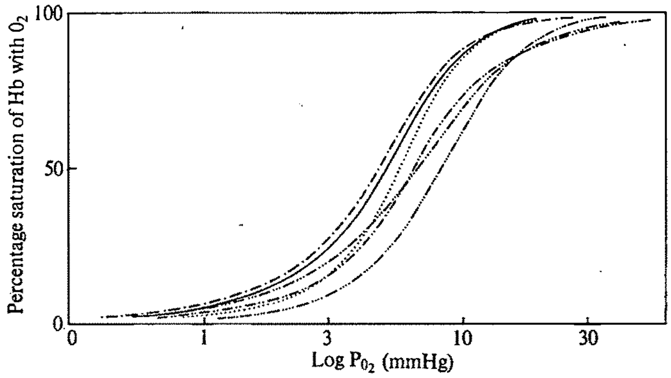

Fig. 1 Oxygen equilibrium curves of haemolysates containing unstable abnormal haemoglobins.

	Concentrations of abnormal haemoglobins	Methaemoglobin concentration before	Methaemoglobin concentration after
· From normal person	——	1.5%	4.0%
– A+Borås	10%	5.5%	7.5%
– · – A+Shepherd's Bush	16%	8.0%	12.0%
– · · – A+Hammersmith	30%	6.5%	12.0%
– · · · – A+Bucuresti	15%	11.5%	13.0%
– · · · · – Lepore Boston+ Peterborough	27% (Lepore) 70% (Peterborough)	2.5%	4.5%

Except for haemoglobins A, Peterborough and Lepore Boston, haemolysates were prepared without the use of organic solvents, with water and dilution appropriate buffers. Haemoglobin Peterborough (Fig. 2) was separated from Lepore and its purity checked by starch gel electrophoresis. Haemoglobin Borås was also separated by starch block electrophoresis; it showed a high oxygen affinity and a Bohr effect, but quantitative data were not obtained. For haemoglobin Shepherd's Bush see Table 2. Oxygen equilibrium curves were determined by the method of Imai *et al.*[7] which involved the use of monochromatic light at 480 nm with haemoglobin at a concentration of 6×10^{-5} M/haem in 0.1 M K_2HPO_4 KH_2PO_4 and 0.5 mM EDTA (pH 7.43±0.02) at 20° C. The concentration of methaemoglobin was checked spectrophotometrically before and after the measurement, using the optical density ratio at 508 nm and 576 nm. The spectra of abnormal methaemoglobins were assumed to be the same as the spectrum of the normal form, and the ratio of the absorption coefficients was assumed to be 3.20 when the methaemoglobin concentration was zero. The concentrations of the abnormal haemoglobins were calculated from optical densities of protein (280 nm) and haem (540 nm) of the cyanomet form in the supernatant after incubating the haemolysate for one hour in 0.05 M Tris-HCl buffer of pH 7.4. The concentrations of haemoglobins Lepore Boston and Peterborough were determined by chromatographic separation. Since carbon tetrachloride was used for preparing the haemolysates for the estimations of fractional concentration, the concentration of the abnormal haemoglobins in the fresh blood may be higher than in the haemolysates.

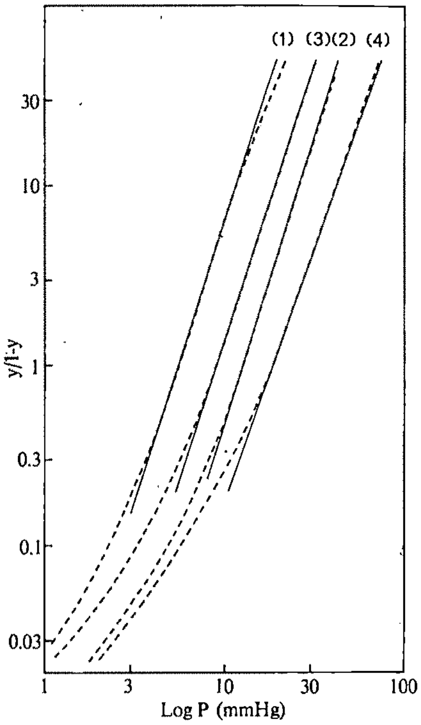

Fig. 2 Hill's constants of haemoglobins A (haemolysate) and Peterborough.

	pH	Hill's constant	Methaemoglobin concentration before	Methaemoglobin concentration after
(1) Haemoglobin A	7.41	3.1	1.0%	2.5%
(2) Haemoglobin A	6.56	3.2	1.0%	2.5%
(3) Haemoglobin Peterborough	7.42	3.0	2.0%	3.5%
(4) Haemoglobin Peterborough	6.56	2.8	4.0%	8.0%

y, Fractional saturation of haemoglobin with oxygen; P, oxygen partial pressure. Conditions as for Fig. 1. The Bohr effect of haemoglobin Peterborough is seen to be normal.

We have considered some cases of abnormal oxygen affinity recorded in the literature, and others recently detected here, which are shown in Figs. 1 and 2. Table 1 lists four substitutions which alter the conformation of the haem pocket: haemoglobins Zürich and Bristol throw light on the part played by the distal histidine E7 which is present in all mammalian haemoglobins (though absent in *Chironomus*[5] and *Aplysia*[6]). Model building suggests that oxygen may not be able to get into or out of the haem pocket unless that histidine swings out of the way; in haemoglobin Zürich it is replaced by arginine which cannot be accommodated in the haem pocket and leaves it open. This gives rise to a very high oxygen affinity. In haemoglobin Bristol, on the other hand, the histidine must be held firmly in position by a salt bridge connecting it to an internal aspartate (E11); this lowers the oxygen affinity, though it is not clear how the oxygen gets in and out at all in these conditions. The substitution of phenylalanine CD1 by serine in haemoglobin Hammersmith and by leucine in Bucuresti may lower the oxygen affinity because the benzene ring of the phenylalanine in haemoglobin A acts as a spacer that stabilizes the haem group

Table 1 Substitution of Residues Directly Affecting the Oxygen Binding Site

References	Designation	Residue		Replacement		Variability	Clinical symptoms	Oxygen affinity (Hill's constant; Bohr effect)	Effect of replacement on equilibrium between deoxy and oxy forms
		No.	Position	from	to				
8, 9	Hammersmith	β42	CD1	Phe	Ser	I	Severe, haemolytic anaemia, splenomegaly. Heinz bodies after splenectomy	Low	The haem group changes its tilt from a more upright position in deoxy to a more inclined one in oxyhaemoglobin. Phe CD1 acts as a spacer that keeps it in the more inclined position; its removal would facilitate the transition to the more upright one in the deoxy form
37	Bucuresti	β42	CD1	Phe	Leu	I	Mild haemolytic anaemia. Spleen palpable	Low	As above
10–12	Zürich	β63	E7	His	Arg	I	Haemolytic inclusion body anaemia on treatment with sulphonamides	Very high (1.8; nearly normal)	The arginine cannot be accommodated in the haem pocket, leaving a large cavity at the ligand site of the iron atom. The haem pocket is wide open
13, 14	Bristol	β67	E11	Val	Asp	I	Haemolytic anaemia with splenomegaly, methaemoglobin formation	Low	Asp at E11 forms a salt bridge with His E7 which would keep the haem pocket tightly closed. Also the carboxyl group would sterically interfere with the bound oxygen
15, 16	Borås	β88	F4	Leu	Arg	I	Mild haemolytic anaemia with splenomegaly. Tendency to methaemoglobin formation	High	The replacement would leave a gap in the haem pocket which apparently makes the haem group more susceptible to autoxidation. This may be the cause of the high oxygen affinity

The positions of all these residues are shown in Fig. 2 of ref. 1. In this and the following tables, Hill's constant and Bohr effect, if determined, are indicated in brackets after the oxygen affinity. References refer to structure, oxygen affinity, and clinical symptoms, in that order. Variability refers to mammalian species only.

Table 2 Substition of Residues Affecting the Balance Between the Two Alternative Tertiary Structures

References	Designation	Residue		Replacement		Variability	Clinical symptoms	Oxygen affinity (Hill's constant; Bohr effect)	Effect of replacement on equilibrium between deoxy and oxy forms
		No.	Position	from	to				
17–19	E	β26	B8	Glu	Lys	I	None in heterozygotes. Mild haemolytic anaemia in homozygotes under stress	Low (normal; normal)	Glu B8β is bound to His G19β in both oxy and deoxy. Its replacement by Lys would introduce a positively charged side chain in oxy where Arg B12β, His G18 and 19β are already closely clustered. In deoxy, on the other hand, the lysyl side chain could be much further away from this cluster. Therefore, the replacement would stabilize the oxy, but not the deoxy, structure
20	Shepherd's Bush	β74	E18	Gly	Asp	V	Mild haemolytic anaemia with splenomegaly	High, P_{50} 3.7 at *p*H 7.4 with P_{50} 6.3 for HbA control; (reduced, 2.5 at *p*H 7.4 with 3.4 for HbA control; normal)	In oxy the side chain of the Asp is easily accommodated, but in deoxy it comes too close to Phe Fl, which would make the tertiary deoxy structure unstable
21, 22	Seattle	β76	E20	Ala	Glu	V	Mild anaemia	Very low (2.1; nearly normal)	Unexplained
23, 24	Agenogi	β90	F6	Glu	Lys	I	None	Low (normal; normal)	Lys F6β could form a salt bridge with the C-terminal carboxyl of the same β-chain in oxyhaemoglobin. This would push tyrosine HC2 into its pocket between helices F and H, which is its deoxy position, and thus lower the oxygen affinity of the β-chains
38	Peterborough	β111	G13	Val	Phe	V	Mild anaemia	Low (normal; normal)	In the deoxy form Phe G13 can be accommodated in the $\alpha_1\beta_1$ contact by displacing the side chain or Gln H5β without further disturbance of the structure. In the oxy form, this is not possible. If oriented towards the $\alpha_1\beta_1$ contact, the side chain of Phe G13 would severely disturb it. If oriented within the β subunit it would make a short contact with Val H12 and produce dislocations. Hence, the replacement would destabilize the oxy, but not the deoxy, structure

The positions of the residue substituted in haemoglobins E and Agenogi are illustrated in Figs. 3 and 4 of ref. 1.

Table 3 Substitution of Residues Affecting the Balance Between the Two Alternative Quaternary Structures

References	Designation	Residue No.	Residue Position	Replacement from	Replacement to	Variability	Clinical symptoms	Oxygen affinity (Hill's constant; Bohr effect)	Effect of replacement on equilibrium between deoxy and oxy forms
25,39	Hirose	β37	C3	Trp	Ser	I	None	Very high (1.5; quarter)	Trp C3β_2 forms a vital part of the $\alpha_1\beta_2$ contact in both forms of haemoglobin. It is in contact with Tyr HC2α_1 in deoxy, and occupies a position such that it would oppose the expulsion of that tyrosine from its pocket between helices F and H which occurs on oxygenation. Removal of Trp C3β would therefore facilitate the transition to the quaternary oxy structure
26*	Malmö	β97	FG4	His	Gln	I	Erythrocytosis	Very high	His FG4 lies at the $\alpha_1\beta_2$ contact but it is not clear why its replacement by Gln should change the oxygen affinity
27, 28	Yakima	β99	G1	Asp	His	I	Erythrocytosis	Very high (1.0; normal)	Asp G1β_2 may be hydrogen bonded to NH of Glu G3β_2 in oxy. In deoxy it is hydrogen bonded to the phenolic OH of Tyr C7α_1. The mutation breaks this important bond in the $\alpha_1\beta_2$ contact of the deoxy form and destabilizes the quaternary structure
29	Kempsey	β99	G1	Asp	Asn	I	Erythrocytosis	Very high	As above
30, 31	Kansas	β103	G4	Asn	Thr	I	Cyanosis	Very low (1.3; present)	Asn G4β_2 forms a hydrogen bond with Asp G1α_1 in oxy. The mutation breaks this important bond in the $\alpha_1\beta_2$ contact of the oxy form and destabilizes the quaternary oxy structure
32	Yoshizuka	β108	G10	Asn	Asp	I	Mild anaemia	Low (normal; reduced)	Asn G10β_1 is in contact with His G10α_1, which lies in a buried position in the $\alpha_1\beta_1$ contact. The replacement of Asn by Asp may lead to the ionization of the histidine, but it is not clear how the degree of ionization would differ in the two alternative quaternary structures

* And personal communication from G. Berglund and T. Leonhardt.

The positions of the residues substituted in haemoglobins Hirose, Malmö, Yakima, Kempsey and Kansas are illustrated in Fig. 8 of ref. 38.

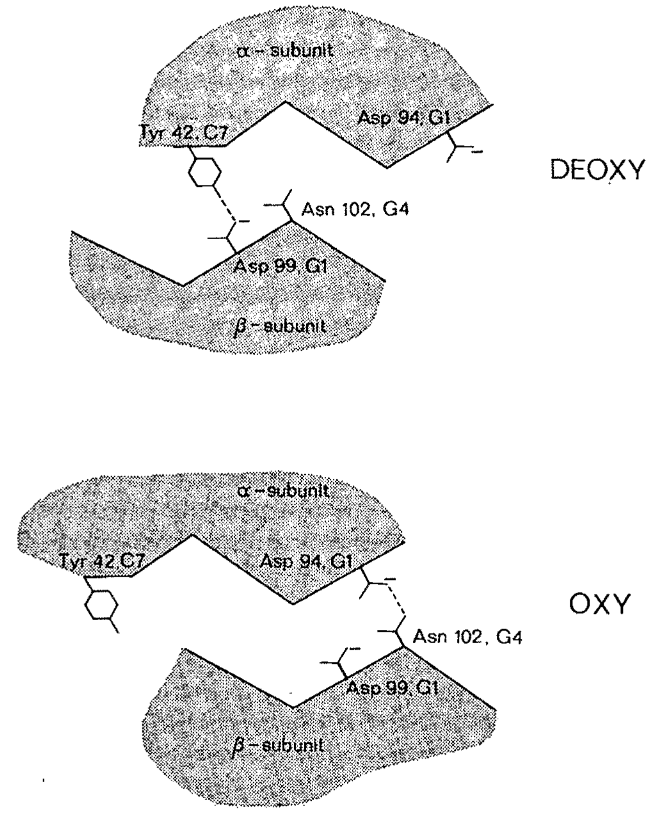

Fig. 3 Change in $\alpha_1\beta_2$ contact on oxygenation. The contact area clicks from one dovetailed position to another, involving a switch of hydrogen bonding as shown. Most of the other contacts are non-polar.

in the more inclined position which it takes up in the tertiary oxy structure. The removal of that ring in the two abnormal haemoglobins may make it easier for the haem group to turn to its more upright position in the deoxy structure.

Among the substitutions affecting the balance between the two alternative tertiary structures listed in Table 2, those of haemoglobins Shepherd's Bush and Peterborough seem to alter the relative free energies of the β subunits in the oxy and deoxy states by purely sterical effects. In Shepherd's Bush the substituted aspartic acid residue is a misfit only in the tertiary deoxy structure, which raises the oxygen affinity, while in Peterborough the substituted phenylalanine is a misfit only in the tertiary oxy structure, which lowers the oxygen affinity. In haemoglobin E the effect seems to be electrostatic, the oxygen affinity being lowered by a cluster of positively charged side chains that destabilizes the oxy structure. The substitution of lysine for glutamic acid in position F6β in haemoglobin Agenogi is interesting because the lysine seems to interact with the C-terminal residues of the β-chain which regulate its oxygen affinity. In deoxyhaemoglobin, tyrosine HC2β is tightly bound in a pocket between helices F and H, but on oxygenation that pocket narrows and the tyrosine is expelled[4]. Any forces which push the tyrosine back into its pocket, such as low *p*H, would also lower the oxygen affinity. Model building shows that a lysine in position F6 could force the tyrosine into its pocket by combining with the C-terminal carboxyl of histidine HC3β. The alanine residue in position E20 is external; its substitution by glutamic acid in haemoglobin Seattle should have no effect on the oxygen affinity. Indeed, an acid group in this position probably occurs in several mammalian species. This haemoglobin may need further study.

The substitutions listed in Table 3 seem to alter the balance of interactions between the subunits. Tyrosine HC2α_1, like the corresponding tyrosine in the β-chain, is wedged into a pocket between helices F and H in the deoxy form and gets expelled on oxygenation. This expulsion is opposed by the indol ring of tryptophan C3β_2. The two residues lie in the $\alpha_1\beta_2$ contact. Replacement of the tryptophan by serine in haemoglobin Hirose would ease the expulsion of the tyrosine and thereby raise the oxygen affinity. It would also open the α_1 and β_2 contact to water and thereby precipitate dissociation into dimers. Kansas, Yakima and Kempsey offer the most striking examples of mutations altering the allosteric equilibrium between the two alternative quaternary structures. They each affect the $\alpha_1\beta_2$ contact in the region between Cα and FGβ where the two subunits slide past each other by several Ångstroms in the course of their reaction with oxygen. In each of the two forms the contact is made up of many van der Waals interactions plus one hydrogen bond (Fig. 3 and Fig. 1 of ref. 3). In deoxyhaemoglobin A that single hydrogen bond is between aspartate G1β_2 and tyrosine C7α_1; in oxyhaemoglobin A it is replaced by another between asparagine G4β_2 and aspartate G1α_1. In Yakima and Kempsey, replacement of aspartate G1β breaks the hydrogen bond that stabilizes the deoxy form, resulting in high oxygen affinity. In Kansas replacement of asparagine G4β by threonine breaks the hydrogen bond that stabilizes the oxy form, resulting in low oxygen affinity (though there may be other factors; Greer found dislocations in the β subunits which may also affect their oxygen affinity[33]).

A diminished Bohr effect has been reported for haemoglobin Yoshizuka. The replaced asparagine residue lies in the $\alpha_1\beta_2$ contact where histidine G10α_1 is normally in contact with the amides of asparagine G10β_1 and glutamine H9β. Replacement of the asparagine by aspartic acid would tend to raise the *pK* of the neighbouring histidine, and if the rise were greater in oxyhaemoglobin than in deoxyhaemoglobin this would oppose the normal Bohr effect. But the atomic models do not suggest any reason why the degree of ionization of histidine G10α in the two forms should differ. The very high oxygen affinity of haemoglobin Malmö is also puzzling. Histidine FG4β is one of the invariant residues at the $\alpha_1\beta_2$ contact, but its part in the allosteric mechanism is still unclear. Similarly, haemoglobins Chesapeake and Capetown in which arginine FG4α is replaced by leucine and glutamine respectively, show high oxygen affinity and low haem–haem interaction which are at present unexplained[34]. Haemoglobin M Iwate has a very low oxygen affinity because it is permanently frozen in the quaternary deoxy structure[36]. Haemoglobins M Milwaukee and Boston also have low oxygen affinities; they are still under X-ray study.

These results show that the equilibrium between the oxy and deoxy forms of haemoglobin can be altered in many ways. One of the two forms may be destabilized because the mutation introduces a bigger side chain which is a misfit in one form but not in the other, or because the mutation leads to a concentration of groups of equal charge which repel each other in one but not the other of the two forms or because it leads to the loss of a hydrogen bond stabilizing one or the other of the two quaternary structures. The equilibrium between the two allosteric forms of the haemoglobin molecule is shown to be very sensitively balanced so that the loss or gain of a single pair of hydrogen bonds has a drastic effect on the oxygen dissociation curve. It is encouraging that even fine modulations of physiological properties of some proteins can now be understood, at least qualitatively, on the basis of atomic models derived from X-ray analysis.

Ecology of the Fossil Hominoidea from the Siwaliks of India

THE ecology of the North Indian *Ramapithecus* has been the subject of recent discussion[1–3]. In such discussion the tectonic framework and uplift of the Himalayas and Siwalik sedimentation during the Miocene must be taken into account. The Middle Miocene is usually correlated with the third major upheaval during which the Himalayas acquired their major features characterized by mountain ranges interspersed by large river valleys and swamps. The bulk of the Nagri fauna associated with *Ramapithecus* is known from Haritalyangar[4]. The ecology can be studied by correlating the extinct mammalian material including *Ramapithecus* with the flora.

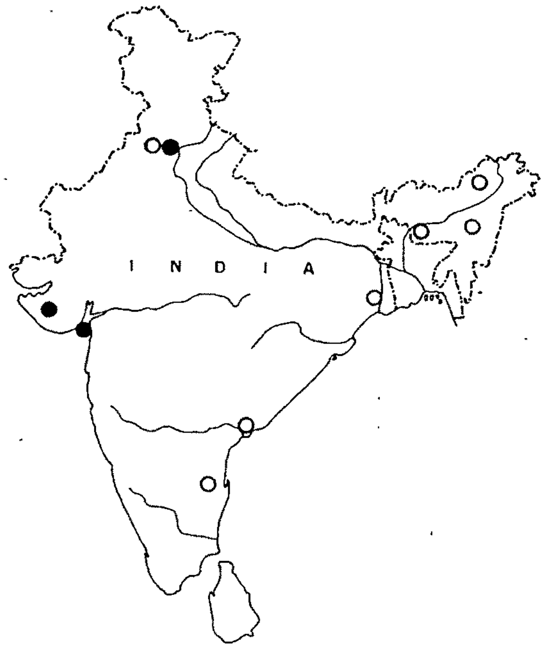

Fig. 1 Floral distribution during the Mio-Pliocene in the Indian region. ○, Miocene; ●, Pliocene.

Two species of *Hipparion* are known from the Nagri beds: the slender, widely occurring *Hipparion antilopinum* may have been a forest browser; the robust *Hipparion theobaldi* apparently preferred an open country environment where forest partially receded especially during the Dhokpathan–Pliocene. *Giraffokeryx*, which is closely allied to *Okapia*, seems to have been a forest dweller, but giraffes are known to prefer open grasslands with scattered trees. The doubtful tubulidentate (*Orycteropus*) could adapt to all types of habitats. The hystrisid and rhyzomyid rodents present in the sediments do not throw sufficient light on environment. The tragulids preferred river banks, whereas the canids and felids could adapt to varying types of habitat. Few typical gazelles are known from Nagri. Convincing evidence for a mixed type of forest vegetation accrues from the presence of dinotheres and true rhinocerotids. It is difficult therefore to draw conclusions about the ecological

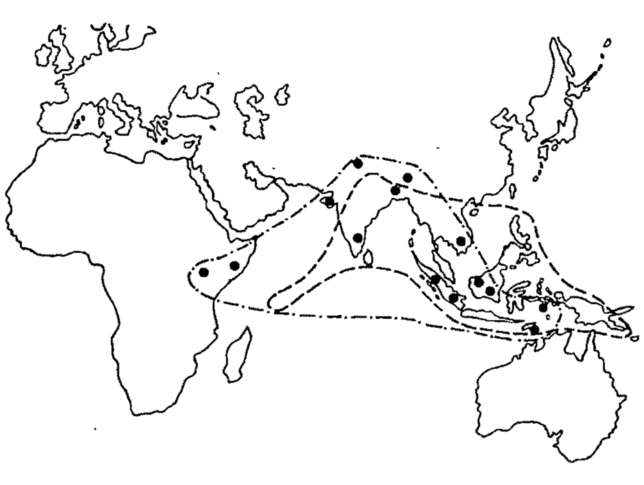

Fig. 2 Distribution of Dipterocarpaceae (modified after Chowdhury, ref. 8). – – –, Distribution today; -·-·-, distribution during the mid Tertiary.

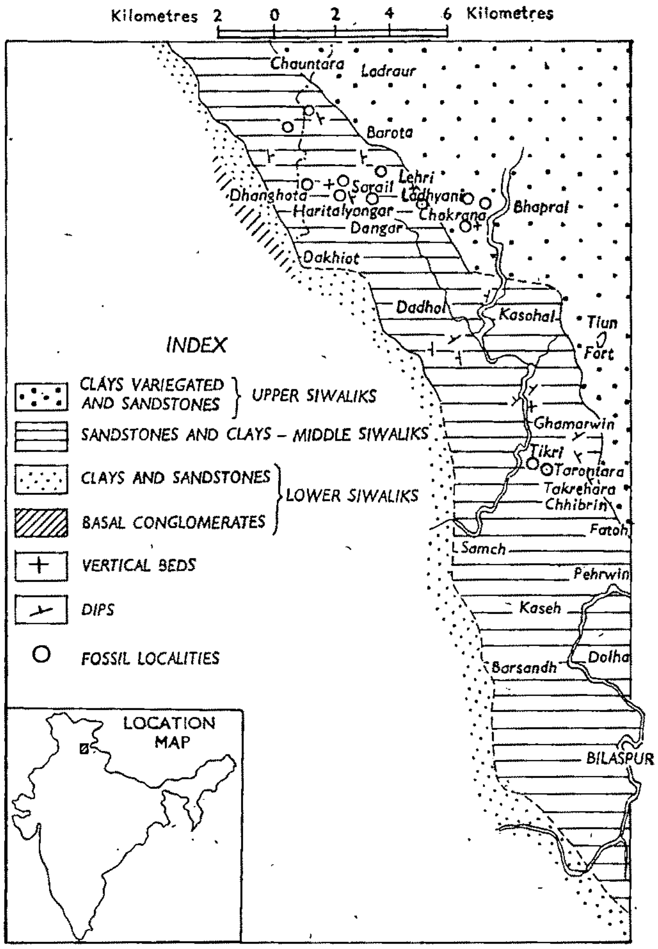

Fig. 3 Geological sketch map of the Bilaspur–Haritalyangar area.

setting of early hominids such as *Ramapithecus* without palaeobotanical evidence.

The evidence for a forest type of habitat in the Miocene lies in the presence of many dicotyledonous woods preserved in the sediments along with extinct mammalian material. Petrified leaf and wood is known from the Siwaliks[5–8]. Miocene flora of evergreen rain forest had a much wider distribution in India during the mid-Tertiary (Fig. 1). *Dipterocarpoxylon* is known from Cutch, the Siwalik Hills of Punjab and foothills region of West Bengal. Fossil woods of Dipterocarpaceae originally distributed in the Malay region are also known from East Africa[8] (see Fig. 2). During the Miocene, *Gluta* was growing in West Bengal and Assam but is now confined to the extreme south-west coast and south Burma. The presence of the moist favouring Dipterocarpaceae and several fossil woods referable to *Mesua, Gluta, Cynometron* and *Calophyllum* in south-east Asia, including the Siwaliks, and in East Africa indicates that the climate during Mio-Pliocene was tropical with plenty of rainfall and supporting heavy forest—fossil woods and other associated floral material are usually considered to be reliable indicators of past climate. The climate seems to have been similar and more or less uniform along the foothills region of the Siwaliks from Assam to Punjab.

Table 1 Distribution of Fossil Dicotyledon Woods in the Tertiary of India (Modified after Ramanujam[9])

Family	Genus and species	Age
Guttiferae	*Kayeoxylon assamicum*	Upper Miocene
	Calophylloseylon eoinophyllum	Middle Miocene
Dipterocarpaceae	*Dipterocarpoxylon garoense*	Upper Miocene
	Dipterocarpoxylon chowdhuryi	Middle Tertiary
	Shoreoxylon evidens	Middle Tertiary
	Anisopteroxylon bengalensis	Sub-Recent
	Anisopteroxylon jwalamukhi	Miocene
Anacardiaceae	*Glutoxylon burmense*	Upper Miocene
	Glutoxylon chowdhuryi	Sub-Recent
	Glutoxylon bengalensis	Pliocene
Leguminosae (Caesalpinae)	*Cynometroxylon indicum*	Upper Miocene
	Pahudioxylon bankuriensis	Upper Miocene
	Pahudioxylon sahnii	Middle Miocene
Combretaceae	*Terminalioxylon chowdhuryi*	Middle Tertiary
	Terminalioxylon tertiarum	Middle Miocene
Ebenaceae	*Ebenoxylon indicum*	Upper Miocene

Leakey[2] asks "Was the very sparse *Ramapithecus* material from the Nagri zone actually excavated from a limited area, at a single level, in association with Lorisids and Pongids?". The Nagri Stage is represented by a thickness of 1,500 m of sediments and most of the fauna have been recovered from various sites within this formation[10,11] (Fig. 3). Tattersall has suggested[1] that it is unlikely that the Nagri hominoids were subjected to heavy predation by social carnivores such as *Crocuta* as propounded by me[4]. Professor G. H. R. Koenigswald (personal communication) has suggested the possibility of predation by crocodiles in addition to hyaenids because numerous crocodilean remains are found in abundance in the Nagri sediments. I suggest therefore that the Nagri environment was one of mixed forest interspersed with streams.

I thank Dr C. G. K. Ramanujam for helpful comments on flora.

Evaluation of Compound Probabilities in Sequential Choice

SITUATIONS frequently occur in which a successful outcome depends on an individual making a correct choice at each of several more or less independent stages. The choice of mode of transport at various stages of a journey is one example. Comparable predicaments occur in professional, administrative, political and military life, and in communication networks generally. The temporal order of the several choices is not invariably a vital factor. Furthermore, the situation as a whole may have a stochastic character in that the probability of correct choice may vary from stage to stage.

We shall describe an experiment simulating this general type of situation, which clearly requires, for a successful outcome, the multiplication of probabilities. Studies[1] of preference for locating a target in an $m \times n$ array, or in a display partitioned into concentric zones, indicate that the cells in the array or the concentric zones are not subjectively equiprobable as locations for the target. Subjects do not seem to guess, at random, the unknown location of the target. Their strategy of search rather has the character of "divining" where the experimenter has hidden it, or of locating it where they would expect it to be. Other experiments[2] suggest that many people, when faced with a situation involving compound probabilities, tend to add, instead of multiply, the chances at the different stages.

We may accordingly predict that in an $m \times n$ array, with an unknown target in each of the m rows, the subject's estimate of his chance of guessing all targets correctly will be exaggerated, as judged by the compound probability, n^{-m}, of locating the target. Our experiment is designed to test this prediction, and to elucidate the phenomena which the situation will generate.

The apparatus consisted of a board on which were set m rows each containing n receptacles, where m and n each took the values 2, 3, 4, 5 or 8. All the receptacles were empty except one in each row which contained a ticket. The number of separate stages therefore ranged from 2 to 8, with the chance of guessing correctly at each stage ranging from 2^{-1} to 2^{-3}.

The subjects were fifty grammar school boys aged 14–15 yr whose "intelligence" may be assumed to be at least as good as that of the average adult. A subject was given to understand that in order to win a prize he had to guess the correct location of the ticket in each row, only one guess per row being allowed. His task was to equate what he thought was the chance of winning the prize with one of a set of lotteries.

There were fourteen lotteries in all. Ten of them had 100 tickets each, the chance of drawing a winning ticket, based on the number of winning tickets in the particular lottery, being 0.01, 0.1, 0.2, 0.3, . . . , 0.9. The remaining four lotteries had 500, 1,000, 5,000 and 10,000 tickets respectively, with the corresponding chance of drawing a winning ticket, 0.002, 0.001, 0.0002 and 0.0001.

The range of values taken by the rows and the range of values of the receptacles allowed for twenty-five different situations. Each of the fifty subjects was assigned at random to five of these situations by means of randomized Latin squares. Ten subjects thus judged each $m \times n$ situation.

The amount of information actually required to locate the target is $m\log_2 n$ "bits", where m is the number of rows, which we will now call "stages", and n the number of receptacles, which will be designated "alternatives". The chance of drawing a winning ticket in the lottery chosen by the subject we shall treat as an indirect estimate of his psychological probability (ψ) of winning a prize.

Table 1 Psychological Probabilities (ψ) based on Choice of Lottery*

No. of alternatives per stage	No. of stages in array 2	3	4	5	8	Mean
2	0.45	0.51	0.36	0.38	0.37	0.41
3	0.41	0.21	0.21	0.21	0.17	0.24
4	0.31	0.23	0.21	0.12	0.11	0.19
5	0.30	0.22	0.17	0.18	0.08	0.19
8	0.07	0.16	0.11	0.13	0.05	0.11
Mean	0.31	0.27	0.21	0.20	0.16	

* Entries in the table represent means of ten observations.

Table 2 Ratios, ψ/p, of Psychological to Compound Probabilities

No. of alternatives per stage	No. of stages in array 2	3	4	5	8
2	1.8	4.0	5.7	12.2	95.0
3	3.8	5.9	17.8	53.2	10^3
4	4.9	14.8	54.0	118.0	7×10^3
5	7.5	27.8	106.0	563.0	3×10^4
8	4.3	82.4	465.0	4×10^3	9×10^5

The results presented in Table 1 indicate that all values of ψ are overestimates, as judged by the compound probabilities, p, thus confirming our prediction. The magnitude of the overestimation is indicated by the ratios of ψ to p in Table 2, which suggests that the realism of the estimates is confounded by an apparent tendency to take less account of the number of stages than of the number of alternatives per stage, although an analysis of variance shows that in relation to the residual variance, both the inter-stage and inter-alternative variances are significant ($P<0.01$).

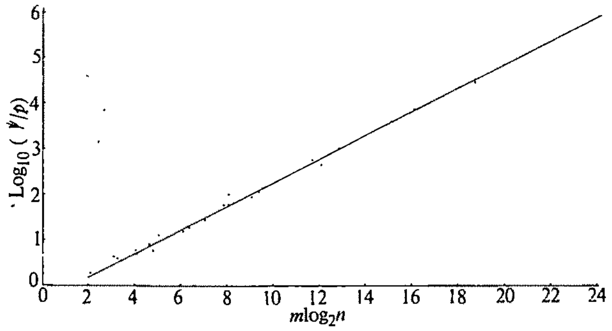

Fig. 1 Log relative overestimation plotted against the number of bits ($\log_{10}(\psi/p)$ against $m\log_2 n$). p, Compound probabilities; m, number of stages; n, number of alternatives.

This differential effect becomes clear if we plot, as in Fig. 1, the logarithm of relative overestimation, $\log_{10}\psi/p$, against the amount of information in bits, $m\log_2 n$, required to locate the target. The relation is linear, and is given by the equation:

$$\log_{10}\psi/p = 0.26\, m\log_2 n - 0.31 \tag{1}$$

This may be re-written as:

$$\psi/p = e^{(0{\cdot}86\, m\log_e n^{-0{\cdot}72})} \tag{2}$$

from which it follows that if we keep the number of stages constant, ψ/p is directly proportional to a power of the number of alternatives per stage, whereas if we keep the number of alternatives constant, ψ/p varies exponentially with the number of stages.

Given m and n, we can predict the mean value of ψ because

$$p = n^{-m} \tag{3}$$

The compound probability p is obtained by multiplying the respective probabilities of guessing correctly at each of the m stages, each of these probabilities being equal to $1/n$.

Therefore, from (2)

$$\psi = e^{-0{\cdot}72}\, n^{-0{\cdot}14\, m} \qquad (e^{-0{\cdot}72} = 0.49) \tag{4}$$

In the main, therefore, the relative overestimation of ψ/p results from a subjective attenuation of the multiplicative factor, m, the number of stages. This attenuation is of the order of six-sevenths of the number of stages, within our experimental constraints. This leads us to infer that the multiplicative element in compound probability is far from being "primitive" or intuitive, which may help to explain the special difficulties which people encounter in the study of statistics.

Our interpretation is supported by similar experiments with subjects aged 9+ and 10+ yr, in which, apart from gross relative overestimation of ψ, no trends are discernible with variations in the values of m and n. This too suggests that the multiplicative element is not primitive.

The method we have used involves an indirect evaluation of ψ. A more direct evaluation could be obtained by asking the subject to choose between different types of array. The utility of the choice, however, might then become an important factor.

This experiment elucidates the apparent tendency, in a variety of multi-stage choice situations, for the decision maker to misjudge the likelihood of his success, and therefore to adopt an inappropriate strategy which he will later regret.

Of historical interest in this connexion is the fact that the most subtle thinkers of ancient Greece, though greatly intrigued by the idea of the possible, especially in Stoic philosophy, never grasped combinatorial analysis, which had to wait until the sixteenth century for its development[3]. Aristotle himself evidently had only a small appreciation of the concept of probability. Whatever intuition of the subject he and others might have had was submerged by long established habits of thought.

The relative overestimation of compound probabilities which the experiment has revealed may be a phenomenon of considerable generality in decision and choice. If so, it merits a special designation. We propose to name it the "inertial ψ effect".

Similarity Measure for Mixed Attribute Types

SUPPOSE we wish to examine the relationships among n objects (units, samples) with respect to m attributes (variates, characters, tests). Such a need arises in geology and archaeology, literary studies, medicine and all the biological sciences, particularly the taxonomy of plants and animals. I define here a numerical measure of similarity between objects that can be applied when any mixture of quantitative and qualitative attributes is involved and when observations are missing.

Quantitative data are frequently presented as an $n \times m$ matrix, X. For many purposes (for example, principal component analysis) the units are regarded as points in Euclidean space, using the Euclidean distance metric

$$d_{ij} = \sum_{k=1}^{m} (x_{ik} - x_{jk})^2 \tag{1}$$

as a measure of the dissimilarity between units i and j. D can be derived from the "similarity" matrix, $W = XX'$, by the relation

$$d_{ij}^2 = \omega_{ii} + \omega_{jj} - 2\omega_{ij} \tag{2}$$

Unfortunately, in many practical situations, some or all of the attributes cannot be expressed in terms of ordered quantitative values, so that W and D cannot immediately be formed. For purely qualitative data, or presence/absence data, there are many coefficients[1] for matching which measure the similarity, s_{ij}, between units i and j. It can be shown that, for many similarity measures, S is positive semi-definite (p.s.d.) so that there exists a quantitative matrix, X_s, such that $X_s X_s' = S$. Thus, S can be regarded as the W matrix for a configuration given by X_s and therefore defines a Euclidean distance matrix by application of equation (2).

A general coefficient of similarity for mixed quantitative and qualitative attributes can be defined as follows.

If attribute k is quantitative, and scaled to have approximately unit range, let

$$s_{ijk} = x_{ik} x_{jk}$$

If attribute k is qualitative, let

$$s_{ijk} = \begin{cases} 0 \text{ when } x_{ik} \neq x_{jk} \\ 0.5 \text{ when } x_{ik} = x_{jk} \end{cases}$$

Then

$$s_{ij} = \frac{1}{m} \sum_{k=1}^{m} s_{ijk}$$

Thus, the measure is a combination of the simple matching coefficients and the W elements for individual attributes.

The resulting matrix, S_m, is certainly p.s.d., because any r-state qualitative attribute can be expressed as $(r-1)$ dummy quantitative variates to give an expanded data matrix, X_e, and $mS_m = X_e X_e'$. We may wish to scale or weight the attributes by factors, f_k, so that

$$s_{ij} = \frac{1}{m} \sum_{k=1}^{m} f_k s_{ijk}$$

This corresponds to scaling the columns of X_e and therefore the similarity matrix remains p.s.d.

The coefficient is additive over attributes or sets of attributes, which allows a recursive definition of the similarity matrix; because, if S_k is the similarity matrix for the first k attributes, and s_k is the similarity matrix for the k^{th} attribute alone, then

$$S_k = \frac{1}{k} ((k-1)S_{k-1} + s_k) \tag{3}$$

Two points should be noted. (1) In general, when quantitative data are involved, self-similarities do not equal a fixed constant, so that the units are not artificially constrained to lie on a hypersphere. There is thus no "horseshoe" effect. (2) As before, we have

$$d_{ij} = (s_{ii} + s_{jj} - 2s_{ij})^{\frac{1}{2}}$$

independent of the origin of the implicit configuration. But, when the similarity matrix itself is required (for example, for a principal component analysis), the elements of S_m must be centred; this is most easily achieved by replacing each s_{ij} by $(s_{ij} - \bar{s}_i - \bar{s}_j + \bar{s})$, where $\bar{s}_i$ is the mean of the i^{th} row of S_m, and $\bar{s}$ is the overall mean[2].

When either or both of x_{ik} and x_{jk} are unknown, s_{ijk} must be estimated. For Gower's similarity measure (first described by Smith[3]) s_{ijk} is set equal to the similarity based on available attribute comparisons between units i and j. This is unsatisfactory, because the m attributes are more or less independent; for example, in a human population, we would hardly be satisfied with an estimate of age similarity based on sex and blood group similarities. Furthermore, the resulting similarity matrix is not necessarily p.s.d., in which case the data cannot be represented in Euclidean space.

For the common attribute distributions, the best estimate of s_{iik} $(=x_{ik}^2)$ is given by the average of the available similarities for attribute k. This corresponds to estimating the original missing value by the mean of attribute k, based on known observations (using dummy values for qualitatives). Thus, S_m remains p.s.d.

A simple example may clarify this. Suppose we have three subjects whose sex, blood group and age are given in Table 1.

Table 1 Sex Characteristics of Three Subjects

Subject	Sex	Blood group	Age	Age/50
1	Male	A	15	0.3
2	Male	A	40	0.8
3	Female	B	60	1.2

Then, using a scaling divisor of 50 for age, we have

$$s_{11}=\tfrac{1}{3}(0.5+0.5+0.09)=0.3633$$

$$s_{12}=\tfrac{1}{3}(0.5+0.5+0.24)=0.4133$$

$$s_{22}=\tfrac{1}{3}(0.5+0.5+0.64)=0.5467$$

so that

$$d_{12}=(0.3633+0.5467-2\times 0.4133)^{\frac{1}{2}}=(0.0834)^{\frac{1}{2}}=0.289.$$

Similarly, $d_{13}=0.968$ and $d_{23}=0.849$.

Suppose, now, that the age of subject 1 is unknown. Estimating age similarities from sex and blood group similarities gives

$$d_{12}=0.216 \text{ and } d_{13}=1.146$$

so that $d_{12}+d_{23}=0.216+0.849=1.065<d_{13}$; in other words, the triangle inequality is not satisfied. But, when we estimate the age of subject 1 to be $\frac{1}{2}(40+60)=50$, or, alternatively, estimate s_{113} $(=x_{13}^2)$ to be $\frac{1}{4}(s_{223}+s_{333}+2\times s_{233})=\frac{1}{4}(0.64+1.44+2\times 0.96)=1.00$, we have $d_{12}=0.116$ and $d_{13}=0.825$.

Nitrogen Fixation and its Significance in Tropical Lake George, Uganda

Tropical lakes have been little studied although they often seem to be very productive, especially at those trophic levels exploitable by man. One such lake, Lake George (0°, 00′, 29° 55′ E) is a shallow lake ($\bar{z}=2.5$ m) with an area of approximately 290 km^2 including the associated channel, and is one of the smaller lakes in the western arm of the Rift Valley of Africa. An important feature of the lake is the high phytoplankton standing crop of approximately 400 mg of chlorophyll a m^{-2}. Yet, in spite of this, there is very little inorganic nitrogen in the water. There is little seasonal variation in species composition, in the numbers of the phytoplankton and in chemical and physical parameters[1,2].

Enrichment experiments have shown that the phytoplankton probably suffer a semi-permanent nitrogen deficiency[3]. An investigation of the supply of nitrogen by direct fixation of N_2 by phytoplankton is consequently of obvious importance. N_2 fixation was measured using a ^{15}N tracer and an acetylene reduction assay[4-8] during wet and dry seasons representative of a full year. A value of 0.008 atom percentage excess over a biological control not exposed to $^{15}N_2$ is significant at the $P=0.05$ level.

Table 1 Seasonal and Depth Variations of Nitrogen Fixation in Lake George

Date (1968)	Incubation depth (cm)	Organic N present (mg l.$^{-1}$)	Atom % excess in sample*	Nitrogen fixed % Fixation (l.$^{-1}$ h^{-1} × 10^3)	(μg l.$^{-1}$ h^{-1})	(mg m^{-2} h^{-1})

* After correction for partial pressure and enrichment of $^{15}N_2$ gas used.

Table 1 shows that N_2 fixation rates of 0.44–1.66 mg N m^{-2} h^{-1} varied irregularly during wet, dry and interseason weather. This contrasts with the pattern in temperate and polar lakes where pronounced peak(s) of N_2 fixation occur during the warm water period[8-12]. The relative maximum rate of fixation, expressed as a proportion of the total amount of nitrogen present, was 0.05% h^{-1} (approximately 0.6% day^{-1}). Satisfactory reasons for these irregular and continuously high rates are not known but the following points are probably influential. First, Lake George diel variations in phytoplanktonic standing crop and productivity can be greater than seasonal changes. Second, the euphotic zone is shallow (60 cm) so that the algae receive irregular amounts of light as they are circulated in and out of the zone. Thus on successive days the physiological state, previous light history and nutrient status of the phytoplankton may often have been different even when the samples were collected at the same time and place.

It is possible that in the afternoon dissolved O_2, which may reach 250% saturation, could reduce the rate of N_2 fixation[13,14]. The frequent pronounced minima of N_2 fixation at 15 cm, which was the depth of maximum photosynthesis during much of the day, may be a direct result of high oxygen concentration, the effect of which must be quite rapid as it was found in both long and short exposure experiments.

The daily fixation against depth profiles reveals a surface maximum, a subsurface maximum at 40 cm and pronounced minima at 15 and 150 cm. This pattern, partially due to crop size, was different from the exponential decrease with depth that occurs in the English Lakes[9] but was more like the pattern found in Tjeukemeer[8] and Clear Lake[15]. Fixation at 150 cm, a region of very low light, was nevertheless appreciable, ranging from 3.8×10^{-30}% h^{-1} (0.09 μg N l.$^{-1}$ h^{-1}) to 30.6×10^{-3}% h^{-1} (0.77 μg N l^{-1} h^{-1}). This consistent fixation at 150 cm requires comment because this was a region with a light intensity well below the photosynthesis/respiration compensation point. The phenomenon of significant fixation in the dark was also found occasionally in the thermally stratified lakes of the English Lake District[9] so that it would seem to be common to a wide variety of waters. Photosynthetic bacteria are present in late summer in the anoxic hypolimnium of eutrophic Esthwaite Water, England (V. G. Collins, personal communication), and may contribute to the high rate of fixation in that lake[9]. By analogy, it is possible that photosynthetic bacteria growing at very low light intensities together with non-photosynthetic heterotrophic bacteria were contributing to fixation at 150 cm in Lake George. Results of diurnal studies of N_2 fixation in Lake George indicate that most of the fixation at 150 cm during daylight occurred in the morning when the oxygen concentration is low. Recent work showing N_2 fixation in the anoxic hypolimnia and sediments of several lakes in North Americ[16,17]a supports the idea of some bacterial contributions to low light fixation in Lake George. But no fixation was observed in illuminated, anoxic, H_2S-producing sediments of the lake and the anoxic zone immediately above the mud is subject to oxygen fluctuations which would deter strict anaerobes. The organism(s) responsible for fixation rates below the photic zone is thus not certain.

No species from the lake was isolated in axenic culture and tested for nitrogen fixation. Fixation was tentatively ascribed to planktonic species of *Anabaena* and *Anabaenopsis*, both of which are suspected to fix nitrogen, although there are few studies concerning pure cultures of truly planktonic blue-green algae. Both these algae were common in the lake[1], and possessed heterocysts, which are correlated with nitrogen fixation in lakes[9,15].

Table 2 Nitrogen Balance Sheet for Lake George—Major Features

Annual gain Source	Amount (mg)	Annual loss Source	Amount (mg)
N_2 fixation	1,280	Denitrification	?
Stream inflow *	322	Stream plankton outflow	3,180
Rainfall	277	Sedimentation	655
Hippopotamus excreta †	76-99	Commercial fish export	50–75

* Minimum values and does not include surface runoff.

† Estimated from sparse knowledge of daily herbage consumption and digestion efficiency[20], extrapolations from cattle urine excretion, and nitrogen analysis of faeces[18].

The annual nitrogen fixation is estimated to be approximately 1,300 Mg for the whole lake, or 44 kg ha^{-1} yr^{-1}. This quantity represents approximately 33% of the lake's annual nitrogen change and thus represents an important factor in the overall budget (Table 2). The details of calculations of nitrogen inflows and outflows from Lake George are given elsewhere[18]. They are based on the flow rates of the principal influents with corrections for direct rainfall and evaporation and the nitrogen content of the mean standing crop of plankton. This high percentage annual contribution is put in perspective when set against the similar value of 38% for Clear Lake, and the considerably lower value of 0.5% for the thermally stratified English lakes[9].

The percentage for Smith Lake, Alaska, was estimated to be 5–10% (Alexander, personal communication); that for Lake Mendota, Wisconsin, is 8.5% (Fitzgerald, personal communication) while that for a Russian Lake[19] was indirectly estimated to be 8%.

It would seem from our results that, in Lake George, the shortage of combined inorganic nitrogen as a nutrient for primary production puts a premium on atmospheric N_2 fixation. The daily rate at which this is carried out (0.6% of total N), although less than the highest values, is within the upper ranges reported for most other waters. More important, the relative constancy of the equatorial climate sustains this rate throughout the year, so the total N_2 fixed becomes extremely important in the nitrogen budget of the lake.

This study is part of a 5 yr International Biological Programme project sponsored by the Royal Society and was undertaken while A. J. H. was in receipt of a grant to study nitrogen fixation *in situ* from the Scientific Research Council. We thank Professors G. E. Fogg, W. D. P. Stewart and Dr J. F. Talling for their help.

Bomb ^{14}C in the Human Population

IN the atmosphere ^{14}C occurs principally as $^{14}CO_2$ and is usually produced by nuclear reactions between cosmic ray neutrons and the nitrogen atoms of the air. The natural equilibrium between production and disintegration of ^{14}C determines a part of the natural background radiation to the human population. From 1955 there has been a gradual increase of ^{14}C in the atmosphere, the land biosphere and the ocean, as a result of nuclear tests. Although ^{14}C was initially not regarded as an important hazard to man[1], it was later pointed out[2–4] that ^{14}C could be a source of appreciable genetic hazard in the world's population, because of its long half life (5,700 yr).

At this laboratory we have studied the ^{14}C concentration in the human body[5]. The correspondence between ^{14}C in the atmosphere and in the human body, mediated as it is by photosynthesis, has been confirmed in 6 yr of measurements[6–8].

Since 1955, about two-thirds of the total nuclear energy liberated in nuclear tests has resulted from tests carried out in the atmosphere at high northern latitudes in 1961 and 1962 (ref. 9). The subsequent transfer of ^{14}C down to the troposphere, the biosphere and the ocean has been followed in detail[10–16]. The ^{14}C excess[16] ($\delta^{14}C$) in the northern troposphere (Fig. 1) is representative chiefly of the region between 30° N and 90° N, although the curve for the southern troposphere is representative of the region from the equator to 90° S.

The model for CO_2 exchange between the various reservoirs is shown in Fig. 2, in which the CO_2 in the troposphere is in exchange with CO_2 in the stratosphere, the land biosphere and the ocean. For CO_2 exchange between the troposphere and the biosphere we share the view of Münnich (for discussion, see ref. 17), who divided the biosphere into two parts. The first (b_1), which consists of leaves, grass, branches, and so on, is in rapid exchange with the troposphere and is combined with this reservoir, but the larger part of the vegetation (b_2) has a much slower exchange rate and is combined with the humus layer.

The ocean is divided into two reservoirs, the mixed layer and the deep ocean. The exchange of CO_2 between the troposphere and the ocean occurs chiefly in the mixed layer, but according to Craig[18] there is also the possibility of a direct exchange with the deep ocean. The ^{14}C concentration in the mixed layer of the ocean is now 10 to 15% above normal[19,20].

Using the model of Fig. 2, we have treated the decrease of $\delta^{14}C$ in the troposphere in a previous article[20]. We showed that the measured variation of $\delta^{14}C$ (x_t) in the troposphere is approximately reproduced by the following two-term exponential function:

$$x_t = A_1 e^{-k_1 t} + A_2 e^{-k_2 t} \qquad (1)$$

in which the parameters A_1, A_2, k_1, and k_2 depend on the various exchange coefficients. Because the errors on some of these coefficients are large, the extrapolation is uncertain and is given in the shaded area of Fig. 1.

The amount of bomb-produced ^{14}C in the atmosphere has increased the total natural amount of ^{14}C in nature by about 3%. According to Harkness *et al.*[8], the production of CO_2 from fossil fuel would lower the natural ^{14}C concentration in the atmosphere to about 16% below normal at the end of this century. It is thus reasonable that the ^{14}C excess caused by the atomic bomb will be more than compensated for by the dilution of inactive carbon (the Suess effect).

The transfer of ^{14}C into the human body depends on the following three factors: (1) the time between the photosynthesis in vegetational food and its consumption; (2) the diet, particularly the amount of vegetational food, and (3) the residence time of the carbon in the constituents of human tissue.

Broecker *et al.*[6] (Fig. 1) found that it took 1 and 1.8 yr before the ^{14}C concentration in blood and lung tissue, respectively, reached that in the atmosphere. They also found that the $\delta^{14}C$ value of blood had a maximum time lag of 6 months behind food.

Berger and collaborators[7,21-23] (Fig. 1) studied chiefly the metabolic turnover time of the constituents of human tissue. For this they used samples from persons who had travelled from the southern to the northern hemisphere. One result of their work was that the incorporation in these people of ^{14}C

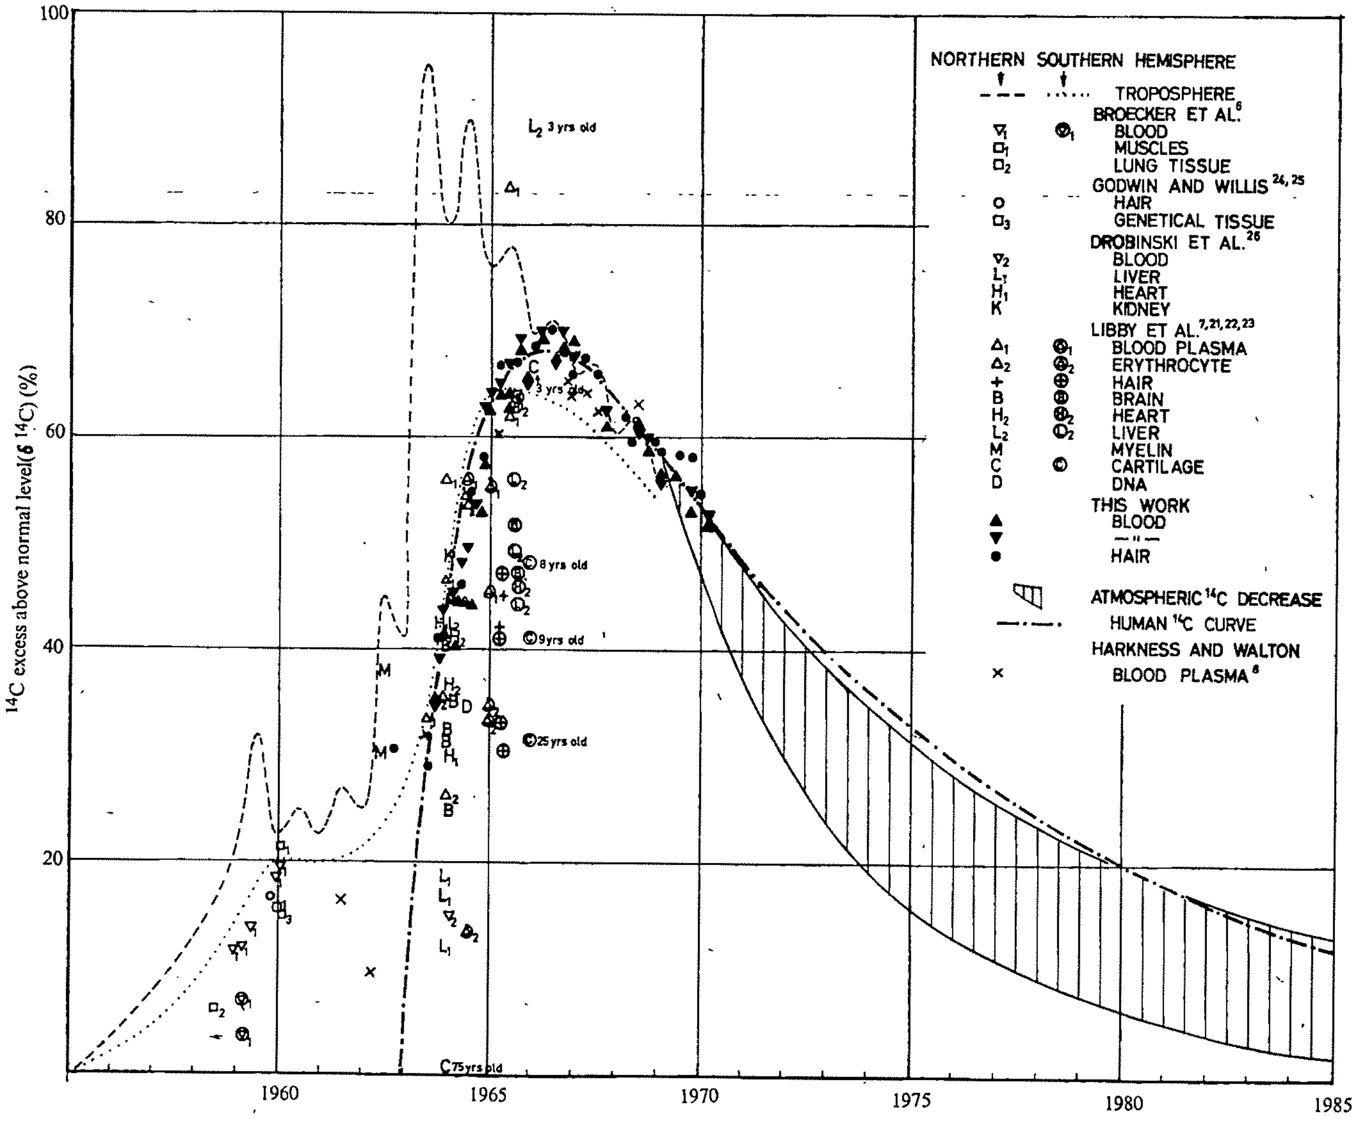

Fig. 1 Radiocarbon in the troposphere and human body.

in brain protein and lipids, liver, heart, plasma protein and erythrocyte protein was very similar to, and reflected, the atmospheric ^{14}C content present several months earlier. Collagen of cartilage was found to be metabolically inert in older persons. The concentration of ^{14}C in the human body has been studied by other workers (refs. 8, 24–26) who obtained values shown in Fig. 1.

At our laboratory the transfer of ^{14}C into the human body was studied by following the time-variation of $\delta^{14}C$ in blood and hair for three persons[5,27] (Tables 1–3). No separation between blood plasma and erythrocyte protein was performed, and the measured ^{14}C activity is thus a mean value for the total blood samples. Fig. 1 shows that there is excellent agreement between data obtained for the blood and for the hair samples. The values of the ^{14}C concentration in blood plasma obtained by Harkness and Walton[8] are slightly lower than ours.

† Not measured (mean value).

The blood and hair data are almost representative for persons living in the northern hemisphere. Because $\delta^{14}C$ in the southern troposphere at present lags behind that of the northern troposphere by about 1 yr, there should also be a similar lag for $\delta^{14}C$ in the human populations of the respective hemispheres. After about 1970, the ^{14}C concentrations in people in the northern and southern hemispheres will be similar, and equal to those in the troposphere. Fig. 1 shows that $\delta^{14}C$ (x_H) in the human body appears as a pulse, delayed with respect to that of the atmosphere. The observed values for x_H can be fitted reasonably well by the following two-term exponential function:

$$x_H = 108\,(e^{-0.1t} - e^{-0.75t}) \qquad (2)$$

The coefficients in this function were determined by a least mean squares method, using the upper limits of the measured values for ^{14}C in the human body in the period from 1963 to 1970, and extrapolated values in the troposphere in the period from 1970 to 2000. The upper limit values were chosen because there was some excess ^{14}C before 1963 which should also be considered. There is also a tendency for the blood and hair data during the last 2 yr to correspond with the upper limit of the shaded area in Fig. 1. Function (2) was simplified by assuming that all previous nuclear tests occurred within a short time interval, and that the ^{14}C increase in the human population started in about January 1963.

The first term in the brackets of equation (2) indicates that the excess ^{14}C in the human body has a mean lifetime of about 10 yr and the second term that ^{14}C enters the human body with a mean delay time of about 1.4 yr after production in the atmosphere. The latter value is probably accurate to within 30% and agrees with previous estimates[6,7].

The hazard to the human population from artificial radiocarbon arises largely from inventory radiation of the body. Natural ^{14}C contributes with a certain dose rate, r_0, as a result of its decay rate of about fourteen disintegrations per min per gram of carbon. The average value of r_0 is about 1.06 mrad yr[9]. The dose from natural ^{14}C is distributed as follows: 1.64 mrad/yr in the bones, 1.15 mrad/yr in the cells lining bone surfaces and 0.71 mrad/yr in bone marrow and soft tissue. Applying function (2), the dose D_t absorbed in the human body during a time t can be calculated from the formula:

$$D_1 = 1.08\, r_0 \int_0^t (e^{-0.1t} - e^{-0.75t})\, dt \qquad (3)$$

For a period of about 30 yr the total radiation dose from this source will be $9r_0$. We thus obtain a total radiation dose of 16 mrad to bone, 11 mrad to cells lining bone surfaces and 7 mrad to bone marrow and soft tissue. The genetic hazard is caused by the latter. That dose constitutes about 10% of the total gonad dose from all radioactive fallout. Purdom[4] pointed out, however, that the actual gonad dose is somewhat larger because of a transmutation process in the DNA molecule, in which the decaying ^{14}C atoms are replaced by nitrogen atoms. Purdom assumed that the biological damage from the transmutation was equal to that from β-radiation.

The amount of artificial ^{14}C in the human body at about the year AD 2000 will constitute about 3% of the total amount of ^{14}C. This isotope has a half-life of 5,700 yr, and several scientists[2,3,9,28] think that it would therefore cause a most serious genetic threat. The long term radiation dose can be calculated from the formula

$$D_2 = 0.03 r_0 \int_0^t e^{-0.000125t}\, dt$$

The total radiation doses ($D_1 + D_2$) which will be received by the bone cells, the cells lining bone surfaces, and the bone marrow and soft tissue in the next 10,000 yr will be 410, 290 and 180 mrad, respectively. These doses, which are in agreement with values given in a United Nations report[9] (page 45), are more important than those from all other radioactive fallout. We question, however, the value of the long term radiation dose (D_2) because, as previously mentioned, the use of fossil fuel might reduce the ^{14}C concentration in man below normal. We are of the opinion that the only ^{14}C hazard from previous tests which should be taken into account is attributable to a total genetic dose (D) of the order of 10 mrad, received in a period of about 30 yr. This dose is, however, negligible compared with the dose received from natural sources, which constitutes about 100 mrad per yr.

Cosmic Ray Flashes in the Eye

THE observations by Apollo astronauts of light flashes in the eye during lunar flights have been interpreted by Fazio *et al.*[1] as Čerenkov radiation. These authors have also considered the possibility of direct stimulation of the retinal cells by the passage of cosmic rays. I wish to show that the observed effects can also be interpreted as scintillations produced in the eye lens by the passage of multiply charged cosmic rays.

It has been found in experiments here that scintillations are produced by alpha particles of 5.3 MeV in eye lenses from freshly killed bullocks. The polonium alpha source was deposited on the tip of a silver wire which was then inserted into the lens. The lens and incorporated alpha source were mounted between a pair of photomultipliers operated in coincidence and easily detectable scintillations were observed. The single electron pulse spectrum was measured by established techniques[2]; using the manufacturer's figure of 10% for the quantum efficiency of the photocathode, the measured maximum pulse height of the scintillations and the known geometry of the experimental arrangement, a figure of 1,000 photons was calculated for the approximate size of the maximum scintillations produced by 5.3 MeV alpha particles along their track length of 40 μm in the eye lens. The higher specific ionization produced by M and H group nuclei in the primary cosmic radiation should produce much larger scintillations for comparatively low particle energies of less than 1 GeV.

Light from such scintillations is of course distributed over the whole interior of the eyeball and it is necessary to postulate some focusing mechanism for some of this light to account for the point flashes reported by astronauts. The water–air interface at the front surface of the cornea will act as a partially reflecting concave mirror for light coming from within the eye. When the eyelid is not in optical contact with the cornea, the percentage of light reflected back into the eye is about 2% and scintillations in the lens will be focused to give an image on the retina. The focusing will be sharp only for certain points within the eye lens and the amount of light reflected back will be limited by the aperture of the pupil of the eye.

For a fully dilated pupil, approximately 0.15% of the light produced in a scintillation in the eye lens will be reflected to give an image on the retina and for a scintillation track of length 60 μm the light reflected will fall within an area of diameter 300 μm on the retina. Taking ten photons as the minimum detectable, a scintillation size of 7,000 photons is therefore required to give a detectable flash. In general, if a particle has sufficient energy to travel through several mm of the eye lens two points along the scintillation track will be brought to sharp focus on the retina, thus producing a double flash. If the eye is closed, reflexion will take place at the inside surface of the eyelid. The partially diffuse nature of this reflexion will mean that the flashes should appear as blobs, though this will be compensated to some extent by the improvement in the fraction of light reflected at this surface.

Scintillations large enough to be visible will be produced only by particles of high charge and relatively low energies (less than 1 GeV). Such particles are below the geomagnetic cut-off for latitudes such as have been used in manned Earth orbiting satellites and it is not to be expected that visible flashes would be reported in such flights. Measurements have not yet been made of the flux of low energy primary cosmic radiation in the regions well away from the Earth, so it is not possible to calculate an expected flash rate. However, taking a figure of 1 per min as the flash frequency observed by the astronauts leads to a flux of particles producing visible scintillations of 7 m^{-2} s^{-1} sr^{-1}, which seems to be of the right order of magnitude.

The number of visible flashes should be considerably increased if the reflexion coefficient at the front surface of the cornea is improved. This can be done by the use of contact lenses which are silvered on the front surface. As D'Arcy and Porter[3] have reported visible flashes seen by dark adapted observers, an attempt was made to see if this effect was enhanced by the wearing of a contact lens aluminized on the front surface. So far it has been possible to do this only with one observer, but flashes of two different sorts have been reported with a low total frequency of about one every 20 min. These flashes were described either as balls of light or as a cloud of light. It is suggested that attempts to confirm these observations might be made in high altitude flights, where there should be an appreciable flux of the primary radiation.

I thank Dr S. McMurry for wearing an aluminized contact lens and reporting on the observed effects, and Dr J. Fitzgerald for depositing the reflecting aluminium on the lens used.

The recent article by Charman *et al.*[4] on the effects observed when 14 MeV neutrons interact in the eye tends to support the scintillation hypothesis because knock-on protons with energies of this order could produce enough photons to be just detectable after reflexion to a dark adapted retina. The streaks reported when the neutron beam enters the eyeball laterally are to be expected since a scintillation track of finite length perpendicular to the lens axis will produce a finite line image on the retina. Knock-on protons produced by 3 MeV neutrons would not, on the basis of the figures quoted earlier, produce visible flashes. This accords with the results obtained by Charman *et al.*[4].

Structure of Acetylcholine

In a recent letter, Chothia and Pauling[1] comment on our paper dealing with the determinants of specificity at cholinergic synapses[2]. They correctly point out that we do not define the conformation of acetylcholine which is responsible for its action at nicotinic sites. Moreover, they present a calculation to show that because the acetylcholine ester grouping is not planar in the conformation shown in the figures, it represents only a negligible proportion of the molecules in solution. From this they conclude that this model of acetylcholine is not relevant to the roles of the molecule as a neurotransmitter.

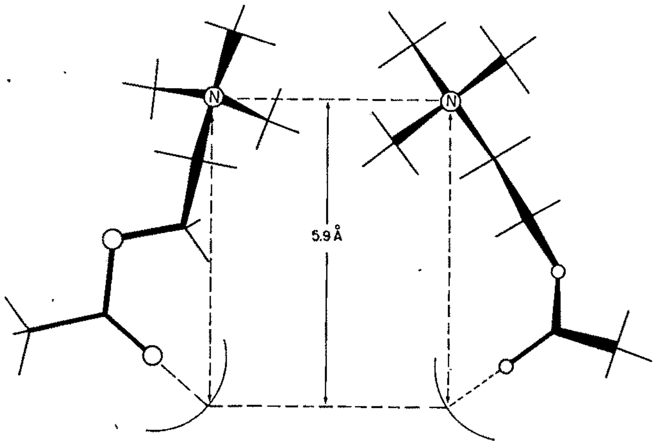

Fig. 1 The drawing used to demonstrate that acetylcholine can meet the proposed requirements for nicotinic activity in our paper is shown here on the right. In the conformation shown on the left the ester group is planar and the requirements are nonetheless fulfilled.

Our analysis is based exclusively on the spatial disposition of functional groups in cholinergic drugs which have either rigid structures or limited degrees of conformational freedom. For each of these drugs we specify and justify a specific conformation. In contrast, we suggest no specific conformation for acetylcholine, and the structure of acetylcholine represented in the diagrams was not intended to imply one. It was meant to demonstrate simply that acetylcholine can fulfil the requirements specified by the rigid drugs, which for the nicotinic receptor is a distance of 5.9 Å between the charge and H-bond. Acetylcholine can meet these restrictions in a very large number of conformations that maintain the atoms in the ester grouping coplanar (Fig. 1). The large number of conformations can be appreciated by recalling that there is essentially free rotation about the O—C bond, that rotation about the bond between the α and β carbons also occurs readily[3] and that hydrogen bonds involving oxygen as the acceptor have few, if any, geometric restrictions[4].

Presence and Function of Disclinations in Surface Coats of Unicellular Organisms

IF a cell which is topologically a sphere is covered with a coat composed of identical units arranged to form a surface crystal, this crystal necessarily[1] contains screw disclinations of total strength +2 complete rotations. Harris and Scriven[2] draw attention to the micrograph of a marine bacterium, *Nitrosomonas*, published by Watson and Remsen[3], on the cover of *Science*, showing a coat of apparently spherical units in close packing. They say that intrinsic disclinations are strongly indicated. We have undertaken further analysis of the disclination structure of this coat.

The structure clearly contains a grain boundary which terminates in the visible part of the coat. Such a termination is a partial disclination. We can show that the visible part of the coat, including the two regions which have apparently been removed in preparation, contains just two disclinations each of strength +1/6. Fig. 1 reproduces the micrograph of Watson and Remsen, with the addition of lines indicating the continuous variation of a lattice direction in the crystal. To analyse the disclination structure, a point was taken that lay between the termination of the grain boundary and the margin of the adjacent missing region. The lattice direction at this point which lies roughly parallel to the long axis of the photograph was taken as the reference direction; this was also assumed to be the long axis of the organism. From this point, two circuits were described, each encircling one of the missing regions counter-clockwise. The lattice direction followed continuously round the circuit has rotated by $\pi/3$ counter-clockwise when the circuit closes. Each circuit therefore contains screw disclinations of total strength +1/6. One disclination is dissociated, and one of its partial disclinations appears as the termination of a grain boundary; the other disclination lies completely within the region which has been removed in preparation.

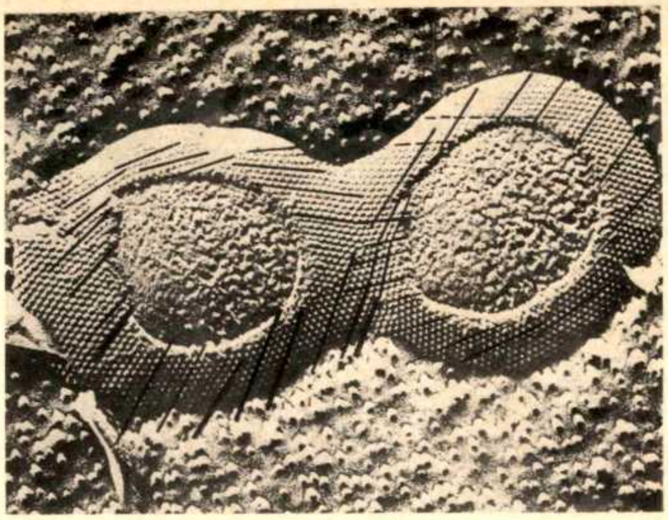

Fig. 1 Micrograph of the coat of *Nitrosomonas* with additional lines indicating the continuous variation in the lattice direction in the crystal.

A disclination of strength $(6-n)/6$ has n-fold rotational symmetry. Thus the addition of two such disclinations, one at each pole, would account for the necessary total strength +12/6 and would fit an assumed n-fold symmetry of the cell. There are exactly two values for n that imply disclinations all of the same strength: $n=5$, with a disclination of strength +1/6 at each pole, and $n=6$ with no disclinations at the poles. The case $n=7$ requires fourteen disclinations of strength +1/6 and two of strength −1/6; all other possible values of n require disclinations at the poles with strengths of magnitude greater than the minimum. Dislocation glide provides a mechanism whereby disclinations can dissociate into disclinations of lower strength and move to lower the total strain energy[2]. Therefore one expects all values of n, other than 5 and 6, to be unlikely. In the micrograph there is no evidence for flattening at the poles as is required if $n=6$. Thus one is left with the most probable result that $n=5$, that is, that there are twelve disclinations each of strength +1/6, including one at each pole.

While the presence of disclinations in coats of this kind is a geometrical necessity, they have no obvious direct biological function. They can, however, act as sources of edge dislocations[2], and edge dislocations are the natural growth points in a surface crystal[4]. This suggests the intriguing possibility of the chemotherapy of diseases associated with the growth of cells having membranes of this kind by the mechanism known to metallurgists as Cottrell locking. A suitable small molecule will be incorporated into the structure at the core of an edge dislocation in preference to an additional unit of the membrane. Further growth at this point is stopped.

Daucic Acid and its Occurrence in Plants

DURING anion-exchange chromatography of extracts of biological materials, acidic non-nucleotide contaminants of the nucleotide fraction have often been encountered. They are usually identified by their characteristic ultraviolet absorption maxima. Thus the leaves of maize (*Zea mays*) were shown to contain chelidonic acid[1], the leaves of wheat (*Triticum sativum*) *trans*-aconitic acid (unpublished results of A. J. K., and M. J. Cornelius) and certain animal tissues ascorbic acid[2]. These compounds were present in sufficient quantities to interfere with ultraviolet analysis of the chromatographic fractions. During a study[3] on the free nucleotides of the root of carrot (*Daucus carota*) another contaminant was observed with a maximum at 240 nm. The spectrum did not change with *p*H until decomposition occurred in highly acid media. The contaminant was eluted with adenosine diphosphate which indicated a strong or multibasic acid.

Bulk quantities of this acid, conveniently named daucic acid, were isolated from carrots (preferably mature) by extraction of the pulped roots with hot water. After the removal of solid material, the acid, together with nucleotide and polysaccharide material, was adsorbed on activated charcoal at *p*H 2. The charcoal was washed with water and the acids desorbed with 0.2 M ammonium hydroxide. The solution was concentrated and the low molecular weight ammonium salt (located by the 240 nm ultraviolet absorption), was separated from nucleotide and polysaccharide material by gel filtration on 'Sephadex G 10'. Further purification was achieved by ion exchange chromatography[4] on 'Dowex-1 X 4' (200–400 mesh). The free acid, liberated using the hydrogen form of a cation-exchange resin, was methylated with diazomethane in methanol–ether. By this procedure, 12.7 kg of carrot roots yielded 460 mg of the diester.

Dimethyl daucate (I; R = Me) had a melting point (in ethyl acetate–light petroleum (boiling point 60–80° C)) of 130–131° C, an $[\alpha]_D^{24.5}$ of −102° (c, 0.9 in acetone), a mass spectrum, M^+ 232, with significant peaks at *m/e* 169, 155, 145 (100%), 139 and 127, a λ_{max} (in ethyl alcohol) at 242 nm (ε 5,600); ν_{max} (in 'Nujol') at 3,500, 1,740, 1,720 and 1,650 cm^{-1} and τ (in $CDCl_3$) 3.96 (1H, m, *H*-3), 5.34 (1H, m, *H*-6), 5.49 (1H, m, *H*-4), 5.70 (1H, m, *H*-5), 6.20 (3H, s, O*Me*), 6.23 (3H, s, O*Me*), 6.72 (2H, m, O*H*). [Found, C, 46.4; H, 5.04; $C_9H_{12}O_7$ requires C, 46.6; H, 5.2%.] INDOR decoupling experiments[5] gave $J_{3,4} = 3$ Hz, $J_{4,5}$ indeterminate, $J_{4,6} = 1$ Hz, $J_{3,5} = 1$ Hz, $J_{3,6} = O$, $J_{5,6} = 2$ Hz. These assignments were supported by a study of the diacetate[7] of the diester of $\tau(C_6D_6)$ 3.98 (1 H, m, *H*-3), 4.15 (1 H, m, *H*-5), 4.37 (1 H, m, *H*-4), 5.65 (1 H, m, *H*-6), 6.56 (6 H, s, O*Me*), 8.21 (6 H, s, $COCH_3$). INDOR experiments[4] gave $J_{3,4} = 2.6$ Hz, $J_{4,5} = 4.4$ Hz, $J_{4,6} = 0.8$ Hz, $J_{3,5} = 1.5$ Hz, $J_{3,6} = O$, $J_{5,6} = 1.8$ Hz.

The diester (I; R = Me) was treated with dry hydrogen chloride in methanol to give a 40% yield of the furan (II; $R^1 = OH$, $R^2 = H$) with a melting point (in ethyl acetate–light petroleum (boiling point 60–80°)) of 134–135°, a mass spectrum, M^+ 214, with significant peaks at m/e 183, 155 (100%) and 122, an $[\alpha]_D^{25}$ of +79° (c, 0.2, acetone), a λ_{max} (in ethyl alcohol) at 256 nm (ε 16,600), ν_{max} ($CHCl_3$) at 3,550, 1,740, 1,720 and 1,600 cm^{-1} and $\tau(CDCl_3)$ 2.93 (1 H, d, J = 4 Hz, *H*-3), 3.58 (1 H, d, J = 4 Hz, *H*-2), 4.80 (1 H, s, α-*H*), 6.16 (3 H, s, O*Me*), 6.23 (3 H, s, O*Me*), 6.74 (1 H, br. s, exchangeable with D_2O, O*H*). The furan (II; $R^1 = OH$, $R^2 = H$) was oxidized with selenium dioxide in refluxing xylene to give, in high yield, the optically inactive ketofuran (all new compounds have been analysed by micro or mass spectral analytical techniques). (II; R^1, $R^2 = O$), m.p. (ethyl acetate) 115–116°, ν_{max} ($CHCl_3$), 1,735, 1,685 $cm.^{-1}$, λ_{max} (EtOH), 293 nm (ε 13,000), mass spectrum M^+ 212, with significant peaks at m/e 181, 153 (100%) and 140, $\tau(CDCl_3)$ 2.20 (1 H, d, J = 4 Hz, *H*-2), 2.63 (1 H, d, J = 4 Hz, *H*-3), 6.45 (3 H, s, O*Me*), 6.60 (3 H, s, O*Me*). The ketofuran was further degraded by oxidation with alkaline hydrogen peroxide to furan −2,5-dicarboxylic acid. The dimethyl ester of this was identical in all respects to authentic material[6].

This correlation established the structure of the methanolysis product of the daucic ester as (II; $R^1 = OH$, $R^2 = H$). This could have arisen from either the dihydropyran structure (I, R = Me) or the dihydrofuran isomer (III). The nuclear magnetic resonance evidence favours structure I and this was confirmed chemically by oxidation of daucic acid methyl ester with chromium trioxide in pyridine to dimethylchelidonate (IV) (40% yield) which was identical in all respects with authentic material. The furanoid compounds (II; R^1, $R^2 = O$) and racemic compounds (II, $R^1 = OH$, $R^2 = H$) were synthesized by conventional methods[7] and found to be identical in all respects to the naturally derived compounds except for the optical activity of the naturally derived (II, $R^1 = OH$, $R^2 = H$). The stereochemistry of daucic acid will be discussed in another report.

Daucic acid has been detected in plants belonging to various other families, in wheat, sugar beet (*Beta vulgaris*), sunflower (*Helianthus annuus*) and tobacco (*Nicotiana tabacum*), and would seem to be widely distributed. The possible relationship to primary metabolic processes is being investigated.

We thank Mr P. N. Jenkins for conducting INDOR experiments, Mr M. J. Cornelius for help with the extraction procedures and Professor J. Edelman for his interest. B. D. B. acknowledges a CAPS award from the Science Research Council and Shell Research Ltd.

BOOK REVIEWS

The Academic Profession

The British Academics. By A. H. Halsey and M. A. Trow. (Society Today and Tomorrow.) Pp. 560. (Faber: London, May 1971.) £5.

"It is virtually impossible that any professor should make the conduct and regulation of his faculty the principal occupation of his life. I myself am a practising barrister—my two immediate predecessors were beneficed clergymen." This is the evidence, before the Royal Commission on Cambridge in 1852, of Henry Main, twenty-third professor of civil law. His evidence was not anomalous: the Royal Commission on Oxford, sitting at the same time, wrote that it was desirable that a university professorship should become "a recognized profession". By 1952 there were some 11,000 professional university teachers in Britain. Today there are more than 30,000: and a graph in Halsey and Trow's book (page 140) predicts an academic profession of some 50,000 by 1980. On this prediction about one in eight hundred of the estimated working population of the United Kingdom would be a university teacher!

So the academics of Britain certainly deserve authoritative and objective study. Halsey and Trow have now provided this study, with a clarity and perception unmatched by any previous writers on the subject. It was not an easy task, for the profession is curiously ambivalent. Its members have a dual loyalty: on one hand, to the "guild" (for want of a better word) of chemists or historians or economists on whose esteem their status in the profession depends; on the other hand, to their avocation to teach in a faculty of the university. Critics of the profession commonly assume that loyalty to the guild takes precedence over loyalty to the student. But it is a profession widely misunderstood, for a simple reason. A lawyer, a doctor, a clergyman, are professionally in touch with ordinary citizens every day. A professor of (say) pure mathematics can achieve an international reputation within his guild without having communicated, professionally, with any except other pure mathematicians. This important book, if people will take the trouble to read it, will go far toward dispelling misunderstanding.

It would be unfair on the authors for a reviewer to try to summarize 560 pages of statistical data and closely argued analysis. Suffice it to say that the book, though expensive even by modern standards, is one which those concerned with decision-making in universities cannot afford to be without. For, as the authors say: "The government is the final arbiter of numbers and money but the university teachers themselves are the managers of expansion. Their assumptions and preoccupations are therefore crucial". And the assumptions and preoccupations of these teachers "shape thousands of unpublished decisions made in colleges and committees, and will continue to influence the rate and form of change in the 1970s". Halsey and Trow, whose views on the sociology of higher education have already won worldwide respect, have painstakingly analysed the motives and prejudices of the academics taking part in the great debate between elitists and expansionists.

After an introduction to "the English idea of a university" (it would be churlish, when the book is already so long, to wish that there had been more about the Scottish idea) the book anatomizes the academic profession (including an entertaining section in which ex-vice-chancellors will wryly recognize their image) into its statistical components: age-structure, pecuniary rewards, social origin and education, and the differentials in emolument and status which still, apparently, persist between Oxford and Cambridge on one hand, and civic universities on the other. The authors then turn to their main theme, which is the attitude of academics toward the expansion of universities in Britain. It is a theme of critical importance. Unless technological civilization collapses, mass higher education is inevitably coming to Britain; any government, left or right, is committed to financing it. But how the finance will be apportioned between university education, as we now understand it, and other forms of higher education (either in universities or elsewhere) is not yet decided. Through the "*crypto-dirigisme*" of the purse, the University Grants Committee, or even the Department of Education and Science, may—probably will—influence this apportionment. But in the long run it is the academics themselves who will determine the educational consequences, as surely as doctors in the health service determine diagnosis and treatment. So to ask how a university teacher's education, social origins, political persuasion, affects his views on university expansion and on the balance between teaching and research is to ask a paramount question. This is the question which Halsey and Trow ask, and answer, for Britain in the late 1960s.

To appreciate their findings in perspective, one must read the book. But in a review for a journal read chiefly by natural scientists it is desirable to offer some reassurance about the methodology and style of a book written by two social scientists. As for methodology, I yield to none in my scepticism about conclusions drawn from sociological questionnaires, and this book is full of tables compiled from replies to questionnaires. But Halsey and Trow followed up their enquiries by intensive interviews. Their experience and objectivity as interviewers are such that the natural scientist's natural suspicions can be put at rest. Another reasonable misgiving which a natural scientist has about sociological observations is that it is difficult to make them as independent of the observer as physical observations can be. What do Halsey and Trow themselves think about élitism versus expansion? And do their views bias their observations? This the reader must be left to decide for himself. Though detecting glimpses of the authors' opinion, I am satisfied that they have achieved a remarkable objectivity.

As for style, there is none of the exasperating jargon (commoner, it is true, from America than from Britain) behind which lesser sociologists conceal the ambiguity of their thoughts. The style is courageously simple and clear. It displays, for posterity, the state of the British academic profession at a critical point in its history.

Eric Ashby

Heartfelt Tale

The History of Coronary Heart Disease. (New Series: Vol. xviii.) By J. O. Leibowitz. Pp. xvii+227+15. (Wellcome Institute: London, December 1970.) £3.

Coronary heart disease is an indiscriminate killer that strikes men down in their prime. In the present century it is one of the scourges of modern life, having replaced smallpox and other infectious diseases as a major hazard to mankind. In medicine, as in other fields of human activity, knowledge of history makes the present more comprehensible even if the future remains unpredictable and, with this in mind, Dr J. O. Leibowitz has written a history of coronary heart disease.

His book provides an excellent background to understanding the present state of medical knowledge in this field. Starting with antiquity and the Middle Ages, he traces the first tentative glimmerings of knowledge of early writers who were concerned on the one hand to define the anatomy and function of the coronary circulation, and on the other to describe individual clinical problems causing sudden death. In the seventeenth century, William Harvey's discovery of the circulation of the blood provided the major physiological breakthrough on which all subsequent development was based. During the next hundred years, an increasing number of clinical reports of individual cases was published and Dr Leibowitz draws attention to a well documented account of rupture of the heart described by Harvey himself in 1649. But it was not until the eighteenth century that advances in clinical medicine and pathology began to parallel those which had taken place earlier in the basic sciences, and Heberden's classical description of angina pectoris, never bettered by any writer since, was published in 1769. Within ten years disease of the coronary arteries was recognized as causing angina pectoris and by the end of the century the work of Parry, Jenner and others had clearly established the relationship between coronary artery disease, angina pectoris and sudden death. The nineteenth century saw the development of cellular and vascular pathology, but only in the twentieth century, with the advent of electrocardiography, was coronary heart disease in its manifold forms fully recognized and Dr Leibowitz unfolds a fascinating story of the developments which have taken place during the past fifty years. Investigation at present is directed specifically to the study of aetiology and prevention, and the book concludes with an up to date account of contemporary thought.

This book is a work of scholarship drawing on the widest possible range of sources and providing an excellent bibliography. Footnotes are well written and unobtrusive, yet provide useful small print information. There is an unexpected error in the identity of a Dr Anonymous who had left his body to Dr Heberden for dissection following his death from angina pectoris in 1772. The autopsy failed to show any abnormality of the heart. Dr Leibowitz identified this public spirited patient as Dr Haygarth of Chester, a physician of outstanding repute in the field of infectious fevers. Haygarth, however, cannot have been Heberden's patient, for he lived on until 1827 when he died in Bath at the advanced age of 87. Such minor points do not detract in any way from the excellence of this scholarly account of one of the major diseases of modern times.

C. C. Booth

Catching the Light

Invertebrate Photoreceptors: a Comparative Analysis. By Jerome J. Wolken. Pp. xi+179. (Academic: New York and London, May 1971.) $9.50; £4.45.

In spite of a generalized title; J. J. Wolken's little book is an illustrative rather than an exhaustive comparative study of invertebrate photoreceptors. By way of introduction the book begins with a description of the electromagnetic spectrum and the physics of light, and this is combined with equally useful information concerning the classification and basic biochemistry of the photosensitive pigments found in plants and animals.

The comparative section begins with that group of animals which has been neglected perhaps the most by photobiologists—the Protozoa—illustrated in this case by the flagellate, *Euglena gracilis*. The fine structures of the flagellum and eyespot are described and experimental details of the animals' photobehaviour are integrated with microspectrophotometric studies of the various organs involved. This is followed by a consideration of the compound eye as found in many insects and Crustacea. Some nine genera of arthropods are described in detail, including the copepod *Copilia*, a species which has become ubiquitous in textbooks of late, presumably because of the perversely unusual visual apparatus it possesses. The invertebrate survey is concluded with a study of the structure of the photoreceptors found in the refracting eye of cephalopod molluscs, such as the squid. It was wise of the author to contrast all the invertebrate structures with the vertebrate retinal rod. The whole forms a good introduction to the study of photoreceptor structure and the subject is made all the more easy to grasp by virtue of the many fine micrographs which form the text figures.

The second part of the book is concerned with the vertebrate and invertebrate visual pigments and deals with techniques for their extraction and purification. The various absorption spectra as measured both *in vitro* and *in vivo* are then presented and discussed, as are similar results for the accessory and screening pigments found in association with the various photoreceptors.

An important generalization in the concluding section is that a functional difference exists between the "open" type of rhabdomere arrangement found in the dipterous insects and the "closed" or fused rhabdomeres of many insects and Crustacea (excepting, of course, *Copilia* which is of the open type). This difference is seen as the adaptation of the closed type to vision at low light intensities, which is fair enough except to say that many insects with closed type rhabdomeres, for example, the bees and wasps, the dragonflies and perhaps the locusts and grasshoppers, are as diurnal in habit as any of the open eyed Diptera. To correlate the structural findings with the electrophysiological evidence the author associates the open eye with the "fast" category of electroretinogram and the closed eye with the "slow" type. Once again the bees are usually considered as having the fast electrical responses, yet are shown to possess the closed rhabdomere arrangement, so that one feels the author should have presented a rather fuller argument for his interpretation of photoreceptor fine structure.

Omitting as it does almost all reference to the electrophysiological events associated with visual excitation, this book leaves the impression of a story unfinished, and this is one reason why *Invertebrate Photoreceptors* remains a good basis for the study of the subject but lacks the breadth to make it a thoroughgoing comparative account.

John Patterson

Snakes of Two Regions

A Field Guide to the Snakes of Southern Africa. By V. F. M. FitzSimons. Pp. 221+12 plates. (Collins: London, January 1971.) £2.10.

The Snakes of Europe. By J. W. Steward. Pp. 238+28 photographs. (David and Charles: Newton Abbot, March 1971.) £2.75.

Europe has thirty-three species of snakes, only five of them confined to the area. There was a general work on European reptiles nearly a hundred years ago and a book devoted to the snakes in particular nearly sixty years ago. Mr Steward brings us up to date on the basis of years of field and vivarium experience and much travel. Southern Africa has three and a half times the number of species, about forty-two of them endemic, and may well have undiscovered forms. Dr FitzSimons's handbook is based on his own pioneering studies in the museum and the field.

Both works recognize a considerable number of subspecies. Although both authors sometimes pause to express doubts about the status of some taxa neither of them discusses the nature of subspecies and makes it clear that they are subjective categories; the existence of zones of intermediacy is barely hinted. Surely the non-specialist would have been better served by an informal survey of the variant regional populations, some of which have been recognized as subspecies. I make this comment partly because I believe that, in many cases, when a larger number of characters is studied, many of them will be found to vary independently and many of the subspecies boundaries be seen to be arbitrary.

Both authors give aids to identification but neither takes the reader gently by the hand through the problems nor mentions museums as a source of information. FitzSimons groups most, but not all, of the snakes by predominant colour and pattern. If one's snake be mostly brown, however, there are fifty-nine to choose from; this can be narrowed further if it be banded, spotted, striped or plain, but a considerable choice would still remain. Steward has a dichotomous key based on simple characters but some of these, for example scale-row counts, are not explained in text or figures. So, in either case, to be reasonably sure, the novice might often finish up scanning the generous illustrations (many in colour for Southern Africa) and wading through individual accounts.

FitzSimons gives a tabular summary of distributions by regions. He gives English and Afrikaans names but only occasionally notices that the snakes have African names. A valuable feature of Steward's book is a distribution map for every species and subspecies. My only comment is that the firmness of the boundary lines can be misleading and is sometimes at variance with the text. There are outline figures of the head scales of most species, unfortunately rather small in relation to the size of the page, and some of them rather vague; several have no nostril. Another valuable feature is a list of the common names in thirteen European languages.

The great value of both of these works lies in the precise description of each form with an account of the habits, where they are known. Sometimes I pause to wonder just how many years of field experience have gone into just a couple of sentences. The books are of about the same size. FitzSimons's work understandably gives more space to snakebite. Perhaps because the European snake fauna is smaller, Steward has more room to discuss the habits of snakes, to interpret their distribution patterns and to convey his personal enthusiasm.

I wish both these works many years of useful service and further editions.

GARTH UNDERWOOD

Hodograph Equations

The Hodograph Equations: an Introduction to the Mathematical Theory of Plane Transonic Flow. By A. R. Manwell. (University Mathematical Monographs.) Pp. ix+476. (Oliver and Boyd: Edinburgh, February 1971.) £10.

ALTHOUGH this book has the title *The Hodograph Equations* it is almost exclusively concerned with the application of the hodograph method to the problem of the plane transonic flow of an inviscid gas. This approach to gas dynamics was pioneered at the beginning of this century by Chaplygin and received a tremendous impetus after the end of the Second World War as the study of transonic phenomena was intensified. The author gives a detailed account of the work up to about 1965. Although slanted to some extent towards the interests of his own considerable contributions to the subject over some twenty years, a very fair overall picture of the subject is presented and the work of the leading research workers such as Tricomi, Lighthill, Guderley, Frankl, Germain and Morawetz, is described in considerable detail. The list of references is not intended to be complete but is highly representative of the major contributions.

The book professes to be aimed at honours graduates in mathematics and engineering, and presupposes a relatively modest knowledge of fluid dynamics and a somewhat more exacting one of classical analysis, although where practicable the author attempts to provide the necessary mathematical background. This leads to lengthy sections on partial differential equations, integral equations and special functions, and accounts in part for the formidable size of the book. Indeed the whole approach is geared primarily to the mathematician, and this is reflected in the preface where it is stated that "the arrangement of the various items is as far as possible in the order of their analytical complexity". This seems a strange principle to adopt as a criterion for ordering and as a result the reader is left with an uneasy impression of having jumped about from one topic to another. With a subject of this nature—relatively narrow from the physicist's standpoint but giving scope for enormous mathematical complexity—the author has a difficult task in that he wishes to present a book which is self-contained and does not require the reader to make constant reference to research papers or other textbooks. At the same time the serious student of the subject may regret the lack of a more extensive bibliography. Professor Manwell writes with the authority of one who has read the literature widely and deeply, and would, one feels, be in a position to supply detailed references, amplified where necessary with expert comment.

Unfortunately, the general impression which the printed format of the book gives is not favourable. The intricate nature of the mathematics calls, perhaps understandably, for the introduction of a plethora of asterisks, bars, tildes, subscripts and superscripts together with a vast range of basic symbols, and there is ample evidence that at times these demands have over-extended the resources of the compositor. Moreover, there are numerous proof reading errors and a complete lack of consistency in the use of symbols, brackets and spaces. A particularly unhappy example is the way in which throughout the entire text a full stop is introduced in a random manner into the middle of mathematical expressions to indicate multiplication. (Equation (14.3) and the line above it illustrate the lack of any consistent pattern.) Other examples are the indiscriminate use of two different founts for the superscript ξ on numerous occasions from p. 59 on, and the fact that the o,O order symbols are sometimes put in italics and sometimes not. Factual errors also occur. For example, in (19.36), $\psi_{(c)}$ does not satisfy Laplace's equation as is required; its compressible analogue in (19.37) is also wrong, and is not even the correct equivalent form of the incorrect version of (19.36). In spite of the inherent interest of much of the material the book is marred by faulty proof reading, poor display of mathematical expressions and indifferent diagrams, and seems overpriced at £10.

A. G. MACKIE

Ancient Astronomy

Ancient Astronomical Observations and the Accelerations of the Earth and Moon. By Robert R. Newton. Pp. xviii +309. (Johns Hopkins: Baltimore, Maryland, and London, December 1970.) £4.75.

IN 1853 J. C. Adams pointed out that the then theoretical value of the gravitational secular acceleration of the Moon's mean motion, which agreed reasonably well with observation, was erroneous and should be reduced to little more than half. The original value stemmed from the combination of the historic discovery by Laplace in 1787 that the secular acceleration was due to the slow diminution in the eccentricity of the Earth's orbit and of a demonstrable error in the analytical derivation (the variable eccentricity had been treated as a constant during the integration of the differential equation). The resulting discordance with observation led to immense activity both in the verification and improvement of the theory, and in the critical examination of the observations.

The discordance could not be resolved since it was due to two distinct but related non-gravitational causes: the variable speed of the rotation of the Earth, giving rise to non-uniformity in the time-scale of mean solar time; the dissipation of energy, and the transfer of angular momentum within the Sun–Earth–Moon system, chiefly due to tidal friction.

In 1939 the Astronomer Royal, H. Spencer Jones, summarized all available data from modern (after 1680) observations of the Sun, Moon and planets and combined these with the results obtained by J. K. Fotheringham from ancient observations. He demonstrated conclusively the reflexion of the Earth's irregular rotation in the motions of the Sun, Moon and planets and determined the so called secular accelerations of the Sun and Moon. The results were subsequently used to define the time-scale of ephemeris time and the adopted secular acceleration of -22.44^{11} (century)$^{-2}$ in the Moon's mean longitude.

In his book R. R. Newton rediscusses the ancient observations and comes to the conclusion (in the opposite sense to Adams) that they support an average value of almost double the currently adopted value. There can be no question either of the importance and value of Newton's contribution or of the impetus that it will give (and, since preprints were widely circulated in September 1968, has given) to research in this field, particularly the analysis of both ancient and modern observations.

The basic unresolved problem is geophysical in respect of the medium term behaviour of the Sun–Moon–Earth system: can the dissipative effects have changed by a factor of 2 in the past 2,000 years, or are either the ancient or modern observations (or analyses, or both) suspect? The question throws doubt on the efficacy of the determination of ephemeris time from observations of the Moon in indicating possible cosmological differences from atomic time. Newton only touches this matter lightly in his final chapter, being otherwise content to present the evidence.

The main part of the book is devoted to a detailed investigation into the records of ancient eclipses and their interpretation. This is a specialist field, much aided now by precise predictions, but involving scholarship of high order and judgment; Newton is very critical of the methods of his predecessors who, in his view, tended to introduce bias by forcing identification. Not all will agree with his interpretations, however; and his methods of analysis are not always as precise as might be desired. But he provides very full information of his sources, his arguments and his treatment; he reviews critically most modern investigations, and he gives a valuable digest of the many confusing notations that have been used. It is a quite invaluable contribution and one that no research worker in either the astronomical or geophysical fields concerned can afford not to have.

Peculiar Stars

Stellar Spectroscopy : Peculiar Stars. By Margherita Hack and Otto Struve. Pp. 317. (Observatorio Astronomico di Trieste: Trieste, 1970.)

THIS book is the second part of the updated revision of a text originally written about ten years ago but not published at the time because of Otto Struve's death in 1963, and it fills a substantial gap by providing a detailed survey of the results of stellar spectroscopy from a chiefly observational point of view. Normal stars were dealt with in the first part of the series.

The concept of peculiar stars is relative: some unusual stars are merely extreme cases of processes in stellar evolution or stellar atmospheres that are believed to be fairly well understood, while other groups of quite frequent occurrence are more or less baffling in the present state of knowledge. Furthermore, it is convenient to group together stars of widely differing evolutionary status having common characteristics such as emission lines. This book accordingly concentrates on three broad classes: hot stars with emission lines; novae and other explosive variables (which also have emission lines); and magnetic, metallic-line and related stars. Other groups like T Tauri and symbiotic stars are mentioned only in passing. The text is partly expository and partly composed of skilfully blended quotations from review articles.

The task of providing a coherent survey of these diverse and only partially understood types of stellar spectrum is difficult, and Mrs Hack has done remarkably well in making the material coherent and reasonably up to date. There are gaps: for example, the possibility of collisional excitation in nova spectra has been ignored and there is no reference to the important work done on non-dipolar fields in magnetic stars. Also some of the arguments used do not have a clear physical basis, particularly on the rather fiendish problems involved in interpreting the behaviour of magnetic spectrum variables. However, the book is a good summary of the observational data in its chosen fields and will provide an excellent starting point for students embarking on an investigation of peculiar stars.

BERNARD PAGEL

Chemical Texts

Physical Methods of Chemistry. Edited by Arnold Weissberger and Bryant W. Rossiter. Part 1A: *Components of Scientific Instruments.* Pp. xi+433. £9.50. Part 1B: *Automatic Recording and Control, Computers in Chemical Research.* Pp. 330. £8. (Techniques of Chemistry, Vol. 1.) (Wiley-Interscience: New York and London, May 1971.)

"TECHNIQUES of Chemistry" is the replacement for the well-known series "Techniques of Organic Chemistry" and the first volume, *Physical Methods of Chemistry,* succeeds *Physical Methods of Organic Chemistry.* Part 1A, *Components of Scientific Instruments,* contains chapters on mechanical and electronic components, the latter being preceded by a chapter on basic electrical principles. Finally, there is a chapter on the generation and modulation of waves (both electromagnetic and acoustic).

The standard of presentation is variable, and in some cases the rate of progress from an elementary start to more sophisticated matter is alarming. Thus, much of the material must appear to be either far too elementary or too difficult for any particular reader. This volume is therefore unlikely to be attractive to individuals and will only find a ready sale to libraries. Even here it would seem that, for a good proportion of the material, likely users will find other specialized texts (not necessarily more advanced) more valuable. It is particularly irritating to find, in a volume as expensive as this, much wasted space. While this is clearly a personal view, I find it difficult to believe that pages of photographs devoted to "view of typical printed circuit card, card rack, hand-wired circuit board, typical multi contact connectors", and such like, can be justified.

Part 1B, *Automatic Recording and Control, Computers in Chemical Research,* contains four chapters. The first, on detection, is principally concerned with various transducers for converting in most instances a change in a particular physical property into an electrical signal, and related matters. I found this chapter interesting and believe that it could be helpful to many. The next very short chapter on automatic recording reads like a collection of technical specifications for various recorders. Such information is freely available, indeed it is difficult to avoid receiving much of it, from manufacturers.

The third chapter, on automatic control, discusses linear feedback control networks, the ways of obtaining data and applications of basic principles to specific systems and the use of feedback for some typical controllers used in chemical apparatus. For those concerned with designing apparatus for chemical research this chapter could be valuable and should enable them to talk sensibly with their senior electronics technicians. The title of the final and longest chapter, "Computers in Chemical Research", is misleading: nearly sixty pages are devoted to Fortran. Surely nobody wishing to learn this language will turn to a book of this type. Similarly, although they make quite easy reading, the history, basic principles and a long and elementary discussion of binary arithmetic and Boolean algebra are out of place in a book about techniques of chemistry. Part of the relatively small fraction of this chapter on digital computers has some real value in the context of this volume. I can imagine very few individuals buying this volume, for more than half of the material is readily available elsewhere at considerably lower cost.

H. M. FREY

CORRESPONDENCE

Science and Development

SIR,—I wish that your discussion of the relevance of science in developing countries (*Nature*, **232**, 73; 1971) could have started some 25 years ago when, after centuries of foreign rule, most of the countries under the old British Empire were beginning to emerge as free nations. It could probably then have saved some of the new governments of those countries from taking decisions which have led to serious economic and social problems. The crying need of millions of people in these countries is for food and shelter and if science and technology has any relevance to humanity then it should be the foremost aim to provide these basic necessities as soon as possible. Development of agriculture and the related industry must therefore be the first task. In order to develop agriculture the research must be oriented to develop better strains of wheat, rice, etc., on one hand and "intermediate" tools of agriculture on the other hand. (What I mean by "intermediate" tools is the sort of tools which are in between the primitive plough drawn by the horse or bullock and the complex tractor.) The intermediate tools would have the advantage that they could be more efficient than the primitive tools used at present and be mechanically simple to be looked after by the simple farmer himself.

Communication to the men in the villages of these countries (and about 80% of the population in a country like India lives in villages) is another equally, if not the most, important aspect to which very little attention has been paid with the result that whatever developments were made in these fields remained confined to reports in the files of government officials.

Without the communication of these new developments to the farmers in the villages, no real progress on the farms can be achieved since it is the farmers in the villages and not the officials who work on the farm. I believe that it is here that the medium of television could provide the means to communicate to the farmer, in his own language, the new developments in tilling the soil, sowing, fertilizers, maintenance of his tools, etc., since any written material, such as books, is no good to him because he cannot read. Even illiteracy could be effectively tackled by the programmes on the television specially designed for this purpose. Italy is known to have achieved, during the last decade, a great success in its agriculture and literacy programme by use of television. I am sure the same can be done in the case of developing nations. Here is a place for the advanced technology in the economics and social advancement of slowly advancing countries.

Education of the illiterate masses through television, I am sure, will make a great impact on the quality of life to millions of people and bring about an awareness of the world around them. As such, at present they are in complete darkness about the better way of life existing a few miles away in their own land, not to mention foreign lands. Television could be used to teach them simple ways and means to improve their own lot and their children's future in the circumstances in which they find themselves. I can visualize the application of television to convince the people of the need to control the population explosion, to improve their sanitary conditions, how to avoid malnutrition with available food. Without the use of this medium, I am afraid, the progress in developing countries will take too long, which would have a disastrous effect the world over. The cost of providing a network of television stations throughout these countries would be well worth the improvements in the lives of millions of people and would be repaid by the increase in production on the farms.

Organized research on an international scale, as you mention, of problems such as health, cheap housing, etc., can easily contribute towards the development of the developing countries. But what is foremost is the need for the realization by the leaders of these nations to orient, in the interest of the people they serve, their policies so as to attract capital from inside and outside the countries in order to enable them to exploit the technology which already exists or is developed by their own efforts for the solution of these problems. This would not only generate the growth of their economies but at the same time enable them gainfully to employ their trained manpower, since unemployment and under-employment of the vast number of the school leavers and graduates lead to serious social problems and no democracy can survive and grow with the existing social conditions of extreme poverty and misery.

Yours faithfully,

K. C. TRIPATHI

Obituary

Sir W. Le Gros Clark

WHEN Wilfrid Le Gros Clark went to Oxford in 1934 (after holding chairs at St Bartholomew's and St Thomas's Hospitals) to become Dr Lee's professor of anatomy at the age of 39, he was already the acknowledged master and leader in three exciting and expanding fields. Largely through the example of his own meticulous and imaginative investigations of the visual and olfactory pathways and of the connexions of the thalamus, descriptive neuroanatomy had begun to make way for much more significant enquiries into cerebral functional organization. The basis of Le Gros Clark's success in this field was laid by his researches into the comparative neurology of lower primates, particularly of tarsier and tree shrews, specimens of which he obtained during his time as principal medical officer in Sarawak (1920–23). This in turn led him deeply into primate and human evolution; his pre-eminence in this field was marked by the publication in 1934 of his influential *Early Forerunners of Man*, later revised in several editions as *The Antecedents of Man* (1959).

His creative and original approaches to neurology, morphology and phylogeny led him on to his reforming activities in both teaching and research in human anatomy and physical anthropology. In anatomy he insisted on experimentation to reveal the functional significance of structure as the way forward. His *Tissues of the Body*, now in its fifth edition, must have reconciled many a medical student to the load placed on him by an over-traditional subject. And he strove for the introduction of shorter textbooks, more in keeping with a modern curriculum, bringing out his own *Practical Anatomy* (1948) and later contributing to the *Text Book of Human*

Anatomy (edited by W. J. Hamilton). Likewise, in physical anthropology, an old-established subject in Oxford, Le Gros Clark firmly opposed the traditional fare of craniometry and typology, advocating instead a genuine study of human variation in relation to both environmental and genetic factors.

All these issues were fostered by him in Oxford over the next 25 years. His vision and integrity, his positive outlook, his critical and creative power, his erudition, his unfailing kindliness, as well as the example of his own sustained productivity, made him an impressive and inspiring head of a large and many sided department. A stream of visitors and postgraduate students came to the department to work with, under, or just near 'Le Gros'.

In the war years a team under his lead demonstrated a new facet of functional anatomy by designing equipment to meet the visual, auditory, manipulative and postural requirements of Service personnel such as gunners performing complex tests of sighting and tracking. This experience of "human engineering" or ergonomics convinced Le Gros Clark of its value for everyday activities, particularly in industry. An MRC unit, attached to his department and of which he was honorary director (1948–1962), pursued a programme devoted largely to practical applications of functional anatomy, human physiology and physical anthropology.

In the last decade of his tenure at Oxford, Le Gros Clark continued his neurological work but became more and more immersed in his palaeontological interests. On a visit to South Africa he was able to study at first hand the australopithecine material, accumulated by Raymond Dart and Robert Broom. He became entirely convinced of the hominid status of these creatures, though he remained sceptical of the proved existence of a form as advanced as *Homo habilis*. He also carried out the definitive descriptions of the pre-hominid material (notably Proconsul) discovered by Louis Leakey. In all this he was never a mere taxonomist, but strove always to define the phylogenetic processes at work. His conclusions on the course of primate and human evolution are set out succinctly in three notable books, *History of the Primates* (8th edition, 1967), *The Fossil Evidence for Human Evolution* (1955), and *Man Apes or Ape Men?* (1967). Le Gros Clark also contributed significantly to the solution of the long standing Piltdown problem (1953).

Somewhat to his surprise Le Gros Clark encountered not inconsiderable opposition both to his reforming activities and to his views on fossil man. Polemics he found distasteful and distressing, but he was a formidable protagonist in controversy, deriving his strength from the painstaking and concentrated consideration and reconsideration he gave to everything he studied.

In some ways Le Gros Clark was a man of paradox. While he went to considerable trouble to discourage the study of anatomical minutiae, he himself retained an awesome knowledge of the detailed macro and micro-anatomy of the human frame and indeed delighted in the art of topographical disquisition. He heartily disliked administration, the role of "organization man" or "scientist-politician" was not to his taste; yet he directed his large department unobtrusively and with efficiency, paying careful attention to its rebuilding, expansion and modernization. He remained a firm believer in simple apparatus and simple experimentation, and often expressed scepticism of the need for expensive equipment, even of the electron microscope; nevertheless when fully convinced, he would spare no trouble to see that the necessary equipment was obtained. For a generation Le Gros Clark was the outstanding British anatomist and its leader, yet he strove always to keep aloof from scientific politics, though in a few crises when he felt impelled to intervene his influence was decisive.

Le Gros Clark was elected to the Royal Society in 1935 and awarded a Royal Medal in 1961. He was president of the International Anatomical Congress at Oxford in 1950, president of the Anatomical Society in 1952 and 1953 and president of the British Association in 1961. He also served on the Medical Research Council. He was a member and master (1954) of the Salters Company and fellow of Hertford College, Oxford. He was knighted in 1955 and retired in 1962. He published a volume of memoirs, *Chant of Pleasant Exploration*, in 1968.

In 1923 he married Freda Constance Giddey, by whom he had two daughters. Freda Le Gros Clark died in 1963. In 1964 he married Violet, widow of Dr Leonard Browne.

The combination of Wilfrid Le Gros Clark's gifts and the diversity of his interests has without doubt made a long-lasting impression on the content and style of British anatomy and allied disciplines.

HOW TO BUY NATURE

Volumes start in January, March, May, July, September and November, but subscriptions may begin at any time.
The direct postal price per subscription is:
12 MONTHS* (52 issues per title)

	Surface Mail UK and worldwide	Airfreight U.S.A.	Airfreight Canada
Nature (Friday)	**£14**	**$48**	**$52**
Nature+ Nature Physical Science	**£24**	**$83**	**$90**
Nature+ Nature New Biology	**£24**	**$83**	**$90**
All three editions	**£29.50**	**$108**	**$116**
Annual Index	**£1**	**$3**	**$3**

* Rates for shorter periods *pro rata* (minimum three months)
(Charge for delivery by air mail on application)

NATURE Volume 232 AUGUST 13 1971

Have We Been Here Before?

ON the face of things at least, the expedition to the Moon two weeks ago was a dramatic vindication of those who have managed, in the past eight years, to keep their faith in the Apollo programme. Nobody will grudge the crew of Apollo 15 the congratulations they deserve for their resourcefulness and persistence. Nobody will pretend that the work that they have done is unimportant—the chances are that after a few months of analysis, the samples now returned from the Moon will help to account for many features of the solar system which are at present annoying puzzles. At the same time, however, it is only proper to insist that what appears now to be the crowning achievement of the Apollo programme is neither a justification of the programme of space development on which the National Aeronautics and Space Administration has embarked nor an argument for thinking that still further rockets should be added to the Apollo series. On the contrary, the way in which the programme appears to have reached a plateaux of achievement is in many ways an incentive for a closer re-examination of what should happen next. Nobody should be surprised if the problem of how to develop a strategy for NASA, sharpened as it has been by the most recent successful expedition to the Moon, seems an echo of the arguments which marked the early sixties.

So far, the direct outcome of the Apollo programme has been four successful landings on the Moon. In simple money terms, each expedition has cost the best part of $4,500 million, comparable with the whole expenditure of the National Science Foundation since the Apollo programme was conceived. Even though there is every reason to applaud the recovery of substantial amounts of rock from the surface of the Moon and although it is beyond dispute that the same samples have added in unique ways to the understanding of the astronomy of this part of the Galaxy, much greater benefits have sprung from the less spectacular sponsorship of basic research in the United States which the National Science Foundation, for all its faults, has undertaken. To say this, is not to pretend that the crew of Apollo 15 risked their necks for nothing or even to deny that there are adventitious benefits—spin-offs as the saying goes—from mounting gigantic enterprises like the Apollo programme. The truth is simply that in circumstances in which scientists must share with all other kinds of mortals a sense that few benefits are obtainable without cost, the undoubted benefits of the Apollo programme are not worth what has been spent on them. Moreover, even now that the system is a going concern, the marginal cost of extra expeditions to the Moon is quite substantial. The Apollo programme is reckoned to cost about $600 million in the financial year that has now begun and will not yield more than two expeditions for such a sum of money. The Glomar Challenger could be operated for the best part of a century on such a budget, and with more valuable results. To acknowledge as much is not in any sense to decry the value of what has been accomplished. It is merely that at a time when all kinds of enterprises for the public good, not simply scientific enterprises, are starved of funds, there is a case for asking whether extravagance is justifiable.

If, however, there remains a case against the continuation of the Apollo programme after the two landings scheduled for the coming year, there is a very much stronger case against the more ambitious scheme to develop a re-usable shuttle rocket aircraft for carrying people and instruments into orbits about the Earth. In retrospect, it is hard to think that even NASA can be happy with the commitment to this enterprise. The most serious objection to the shuttle project is to know what useful purpose it will accomplish. Two years ago, it is quite clear, the intended function of the shuttle project was to keep NASA's image burning bright. With the impending end of the Apollo programme and with a danger that no amount of success would persuade Congress to continue the exploration of the Moon, NASA considered it would be prudent to have a large and indivisible programme with which to make a claim on public funds. Although there is something in the argument that a single coordinated programme of development is likely to provide a more identifiable focus for the activities of great teams of technical people, the overriding weakness of the concept of the shuttle is that it is almost certain to turn out to be a project which it is more fun to work on than to complete. Briefly, although in theory a re-usable shuttle would be a powerful means of reducing the average cost of a space launching, these benefits are most likely to be apparent for comparatively low orbits about the Earth and are in any case unattainable if there is not a sufficient volume of launching work to do. And even if Congress should allow NASA to go the whole hog and to make a functioning shuttle by the late seventies, it is exceedingly improbable that there will also be money to launch such a large number of orbiting Earth stations that one or two of the shuttle machines could be economically employed on servicing them. Far from being the workhorse of space exploration, the shuttle is well on the way to becoming the white elephant.

Luckily, it now appears that the dogmatic line of the past year is being modified. At the beginning of June, the new administrator of NASA, Dr James C. Fletcher, let it be known that NASA was seriously considering the use of conventional rocket boosters to launch upper stages capable of attaining orbits about the Earth but of returning under their own wings. On this view, it would be possible to keep the cost of the shuttle programme within more modest limits. With luck, the annual cost might be a mere $1,300 million and not the maximum of somewhere between $1,600 and $1,800 million originally expected in 1976–77. This modification, apparently devised by the Grumman Company, is obviously a departure from the simple concept of an entirely re-usable rocket—indeed, not merely would the booster be the lowest stage of a Saturn rocket of the kind used in the Apollo programme but the fuel tanks for the upper stage would also be jettisoned as they were emptied.

By making the shuttle half a shuttle, NASA has also made it possible for Congress to say that it will pay for one half and not the other. That is what NASA should now admit. And given the possibility that hidden snags may further delay what is, after all, an exceedingly complicated programme, it is entirely possible that the full-blown shuttle, re-usable booster and all, will be a plaything for the eighties, not the seventies. Two years ago, when the project was first launched, such a course was advocated by NASA's critics as the prudent course to take. If events have forced NASA to take this path, so much the better. And it is only fair to say that a comparatively modest approach to the design of the shuttle and in particular the use of the upper stage as a means of testing the recovery of gliding aircraft from a height of 100 miles or so would be technically quite valuable. Whether the same machinery is needed to service the orbiting houses called Skylab is another matter. After all, conventional rockets such as Saturn can do just that. At this point in the development of these advanced programmes, would it not be much more prudent for NASA to aim at a degree of flexibility in its planning? In short, is there not a case for deciding now that the Saturn rocket will remain the workhorse of the large booster programme in the United States, at least until 1975, when prototypes of the shuttle engine will have been flown? That will be soon enough to define the parameters of the next generation of large space rockets. By then, NASA may have a clearer idea of what it wishes to achieve.

What should that be? The first thing to say is that there has never in the past ten years been a scheme for the use of satellites and rockets that compared in attractiveness with the oldest proposal of all for putting satellites to work—the scheme for communications satellites first suggested by Mr Arthur Clarke immediately after the Second World War. By comparison, even weather satellites are less obvious pieces of machinery, whereas the scheme for using satellites to identify the constituents of the Earth's crust and even to spot corn blight in the Middle West has an air of desperate unreality. The best use so far suggested for Skylab is in X-ray astronomy and, although the scientific community is unlikely to look such a gift horse in the mouth, who would seriously claim that such an expenditure of money will bring a commensurate return? Although in the past two months it must have seemed to NASA that its constituency was being undermined by economic pressures and the scarcity of public money, by technical setbacks (of which there have been precious few) and by the wayward disaffection of American taxpayers, the truth is that its most serious weakness is the lack of an obvious goal at which to aim. In a funny way, NASA is ahead of its time, perhaps even a decade ahead. In the circumstances, it should concentrate on two quite separate objectives. First, there is the development of more sophisticated kinds of rockets for the exploration of the solar system—it is a great misfortune that enterprises such as the Grand Tour of the planets should in present circumstances have to wait until the astrologers say that the planets are properly placed. Second, there is a great deal of useful exploration to be done with existing hardware, near the Earth, on the surface of the Moon and in the directions of the nearer planets. If NASA had the strength to wash its hands of the shuttle except in the most truncated sense, it might yet win back its admired place in the scheme of things.

Throwing in the Sponge

ALL managers of research and development are well aware that the most difficult part of their job is to know when to abandon projects to stop throwing good money after bad. Ever since the managers of research began to acknowledge, in the late fifties and early sixties, that it is possible to set about objectively to understand the process by means of which a bright idea becomes a marketable product, they and those who act as their critics have been on the look-out for ways of codifying the structure of research and development. In the early sixties, the Gibbs–Zuckerman report, originally written as a means of instructing the British Government in the management of its own research facilities, put forward the then fresh discovery that the process of research and development necessarily involves the attrition of bright ideas. A company may set off enthusiastically after a dozen different hares, and may spend quite large sums of money on each of them, but if it is to be reckoned a serious business enterprise, the time will come when it will have to abandon the majority of its research enterprises so as to concentrate on the technical and commercial development of one or two of them. More recently, in the United States, the Charpie report put the same point differently—the successful small companies are those with self-restraint enough to concentrate their energies at the points at which they are likely to be profitable. In Britain, the issue has most recently been taken up by an organization called the Centre for the Study of Industrial Innovation, and in particular Dr W. Duncan Reekie of the University of Edinburgh has set out to look at a third aspect of the problem—the abandoned projects and the reasons why they were abandoned (Centre for the Study of Industrial Innovation, 162 Regent Street, London W1R 6DD, *On the shelf: a Survey of Industrial R and D Projects Abandoned for Non-Technical Reasons*, £0.50). Unhappily, the report is rich on detail and poor on analysis and generalization, with the result that those who read it will be well supplied with anecdotes that other people have made but perhaps even misled by what the survey has to say about the principles to be adopted in the management of research and development.

The centre was lucky enough to have a good response to a series of enquiries among companies in the United Kingdom—twenty of them were visited and talked to. To read between the lines, the companies concerned seem to have been rather glad of an opportunity of bringing their skeletons out of the cupboard. In a laconic summary of these confessions, the report explains how a company that set out to make an acid-resistant paint found that the research was successful but the price too high, that the successful development of an axial feed pump for feeding water into boilers under pressure had to be abandoned because the only customer changed his mind, a scaled down version of the huge machine that levelled land on highway projects was abandoned because it turned out for one thing to be too expensive for the potential customer and because it was either too heavy or too light for the applications in which its use had been suggested, and a sophisticated system of design for a voltmeter came to nothing, partly because the sophistication turned out to cost more money than the designers had hoped and partly because the manufacturer, in any case, made quite satisfactory voltmeters in the first place. None of these case studies will surprise those who work in industrial research and development in Britain, the United States or elsewhere. None of them, indeed, will seem anything but a part of the unavoidable ups and downs of commercial life.

In circumstances like these, what morals can be drawn from the abandoned projects described by Dr Reekie? His own conclusions are that the reasons for abandoning a project were usually extrinsic to the company concerned. Sometimes the market would turn out to be too small—and there is some evidence that British companies often find it hard to make a market bigger by promotion. Sometimes companies seem to have embarked on technical developments which were frustrated not merely by changes of mind by monopoly buyers but also without adequate assurance that a potential customer was in a position to buy. Other projects seem to have been abandoned because, when all the figures were available, it turned out that potential competitors were already selling competitively. And then there were problems about uncertainties over the supply of materials or the durability of the product of a successful development campaign. One way and another, Dr Reekie seems to have been given a comprehensive tour of the field in which industrial companies are required by the wish to stay in business to make decisions about the deployment of their resources on research and development.

The flaw in Dr Reekie's paper is its innocence. For decades now, in Britain, it has been customary to wring hands whenever a research project is abandoned, shedding tears not merely for the money that might have been spent elsewhere but for the manpower that has been wasted. In part, the explanation is that technical resources of all kinds were exceedingly scarce in the days immediately after the Second World War, so that there came about a tendency to regard them as a non-renewable resource to be spread as thinly as possible. The result is that even successful research and development projects in Britain are understaffed. Dr Reekie has picked out a few cases on his list where structural weaknesses in the organization of a company account for the failure of a research project, but it is earnestly to be hoped that the appearance of his report will not discourage companies elsewhere from taking the view that abandoned research projects are not merely inescapable, given the uncertainties of commercial life, but that a lack of them probably implies either that too many projects are being carried through to development, with the risk that financial resources will be overstrained, or that nothing worthwhile is happening.

Howzat!

THE grievous condition of cricket, and the agonies of the Marylebone Cricket Club, should not go unremarked simply because British athletes, youths and schoolboys have begun kicking leather balls between upright sticks of wood. In the past year, the pretence has been abandoned that the game of cricket is an open-ended business—teams will open hostilities against each other on a Thursday morning and not be finished until the following Tuesday. Instead there are now games of cricket in which only a few hours are set aside for play and often all this happens, historians will record with fascination, on Sundays. The whole objective seems to be to make the game more fun to watch without robbing it of that contemplative air which in the past has been calculated to keep the spectators away.

If the managers of the game are serious, they should take more radical steps to keep cricket alive. It is several years now since the Marylebone Cricket Club turned down a proposal for a cricket ball with a moment of inertia much greater than is at present possible, with the result that spin bowlers would be more effective or at least more puzzling to batsmen. There is no reason why it should not in the 1970s experiment with cricket pitches that are shorter, wicket to wicket, than the standard 22 yards (which is, after all, a non-metric measure—who now knows what a chain is ?). Presumably batsmen would score less for lack of time to play elegant shots but would on the other hand be able to scamper more quickly between the wickets and be less in danger of being run out. Other innovations that come readily to mind are larger cricket stumps, thinner (or thicker) bats and shorter boundaries. The MCC should give particular attention to the last of these, for it is well known that the spectators are especially delighted whenever a player strikes a cricket ball over the boundary. On the principle of rendering to Caesar what he paid to come to see, is it not time that even bad batsmen were enabled to hit a six ?

100 Years Ago

THE GUN-COTTON EXPLOSION AT STOWMARKET

THE disastrous explosion of gun-cotton, which occurred on Friday last on the premises of the Patent Safety Gun-cotton Company, is a calamity of unusual significance. Besides the large number of killed, amounting, we believe, to five-and-twenty persons in all, there were as many as seventy maimed and injured, many of them too, in such a manner as only violent explosions are known to torture and lacerate their victims ; and when it is taken into consideration that in all probability a dozen tons of the material actually exploded, the grave nature of the accident is in truth not surprising. The whole group of factory-buildings and out-houses were levelled to the earth at one fell swoop, and for miles away the effect of the catastrophe was acutely felt.

But it is not only from a social point of view that the affair is to be deplored. As a result seriously affecting the science of explosives, the occurrence is peculiarly unfortunate ; for the belief in the safety of gun-cotton as an industrial and military agent will now be gravely shaken. It is all very well for scientific men to adduce a plausible reason for the occurrence, and to prove conclusively that with due care and precaution a disaster of this nature could not possibly have happened ; but the public unfortunately will not be satisfied with a theoretical assurance of this kind ; and indeed measures should certainly be taken, not only to guard against such wholesale death and destruction, but to render the same absolutely impossible.

From Nature, **4**, 309, *August* 17, 1871

OLD WORLD

NUCLEAR WEAPONS

Aldermaston Decision

THE decision that the Atomic Weapons Research Establishment at Aldermaston should be transferred from the Atomic Energy Authority to the Ministry of Defence, anticipated as long ago as April by the Rayner report, was announced on August 5 by Mr John Davies, the Minister for Trade and Industry. This brings to an end a period of great uncertainty at Aldermaston which goes back to the early sixties and the abandonment of the advanced strategic weapons systems then being developed in the United Kingdom—the Blue Streak missile and the warheads that were to have been fitted to the Skybolt air-to-ground missile. For the past few years, it has been increasingly apparent that if Aldermaston has a place anywhere in the British Government's arrangements for research and development, it is with the Ministry of Defence and not the Atomic Energy Authority.

According to the statements last week in the House of Commons and the House of Lords, the government expects that the necessary legislation to transfer the Aldermaston establishment to the Ministry of Defence will have been dealt with in time for the transfer to be complete by the summer of 1972. The government has promised to consult the staff and trade union representatives about how the transfer will affect people's jobs, and Lord Carrington, the Minister of Defence, said that "the general aim will be that the terms and conditions taken as a whole shall be no less favourable than those provided for in existing contracts". At present, something like 19 per cent of the expenditure at Aldermaston concerns projects which are not part of the military programme, and 10 per cent of this work is nuclear in character. The government has been at pains to emphasize that the transfer to the Ministry of Defence will not necessarily reduce the amount of non-military work carried out at Aldermaston, but in future, projects such as those undertaken for the development of the fast reactor programme, will be covered by contracts placed with Aldermaston by the Atomic Energy Authority or one of its dependants.

Mr Anthony Wedgwood Benn, previously responsible as Minister of Technology for the Atomic Energy Authority, complained that it would be dangerous to go against the example shown by most other countries in the West by putting the nuclear weapons research directly under the military, and that the transfer would in any case spoil opportunities for further diversifying the work of the establishment.

So far, there is very little to suggest how the remainder of the Atomic Energy Authority will be affected by the impending reorganization of government research establishments, although a statement last week did say that the government is considering "how best the electricity supply industry and the nuclear industry could be more closely involved in reactor research and development". This formula can, of course, mean anything from the transfer of the reactor development station at Winfrith to the Central Electricity Generating Board, to the amalgamation of the design group of the Atomic Energy Authority with the Central Electricity Generating Board. Now that the fuel manufacturing capacity of the authority has been embodied in British Nuclear Fuels Limited; the way would seem to be open for a daring administrator to bring the Atomic Energy Authority entirely to an end.

SCIENTISTS' PAY

Mighty McCall

MORE than 3,000 disgruntled government scientists gathered in Central Hall, Westminster, last Tuesday in the final meeting organized by the Institution of Professional Civil Servants to protest against the government's pay offer. The purpose of the meeting was to give point to the outrage that scientists in the Civil Service have been expressing about the recent pay award.

Mr William McCall, the general secretary of the IPCS, said that the meeting was the biggest in the history of the IPCS and that there were larger issues behind this dispute. Mr McCall complained that the government was taking advantage of the economic situation and of the extensive unemployment among scientists to depress the pay of scientists. The implications of the government's offer, added Mr McCall, spell disaster for the national economy.

Indirectly, 27,000 scientists are affected by the offer and of these 17,000 are being offered no pay increase (Table 1). Mr McCall claimed that the government's treatment of the pay claim fits into a determined policy to reduce the size of pay increases. The offer of the Civil Service Department, said Mr McCall, was a declaration of war—an attack on the living standards of scientists. No other group in Britain has this year been offered no increase at all, he said; the offer means a cut of 10 per cent in the living standards of scientists. Mr McCall went on to say that as the government employed 27 per cent of all scientists in Britain, its attitude will make the pay of scientists everywhere go down and the ability of the country to make science an attractive profession will be impaired.

Mr McCall also complained that the government has never turned its back so completely on arguments advanced by the IPCS—which does not augur well for the status of the scientist in Britain. The institution's interpretation of the report of the Pay Research Unit differs profoundly from that of the Civil Service Department. Mr McCall pointed out that after investigation by his office it was revealed that the average age of the "equivalent" scientist employed in industry was nine years younger than in the Civil Service. This younger age reflected the better chances of promotion of a man in industry and if nine incre-

Table 1 The IPCS Claim and the Government's Offer

	490	550 (12.2%)	7.1%

ments were added to the salary of the government scientist it would then be a fair comparison.

One of the implications of this offer that worries the IPCS is that it will not be practical to implement the Fulton report on the restructuring of the Civil Service if the scientists' salaries fall much below those of the equivalent grades in the administration and engineering classes. If the Principal Scientific Officer gets no increased offer then his salary will be £500 less than the other grades within the service and an amalgamation of the grades will thus prove impossible.

Mr McCall was given a tumultuous acclamation by the scientists that packed the hall. The meeting, however, could only be regarded as a show of strength as no better offer was received by the IPCS before the official tribunal sat yesterday, August 12, to arbitrate the dispute Mr M. J. Mustill, QC, the chairman, is expected to announce the tribunal's decision early next week and Mr William McCall will certainly be a very disappointed man if no better offer than that already made by the government is recommended.

ENZYME RESEARCH

More Chemists Needed

The Science Research Council has come out with a declaration that more should be done to interest undergraduates in enzyme chemistry and technology and that practising chemists should be encouraged to devote their special skills to the subject. These points emerge from a review carried out by the Enzyme Chemistry and Technology Committee of the Science Research Council (*Support of Enzyme Chemistry and Technology 1969–71*, Science Research Council, 1971). The committee, under the chairmanship of Professor Sir Ewart Jones, was set up in 1969 following recommendations of a specialist panel of the Science Board.

The continuing importance which the SRC attaches to interdisciplinary research is indicated by the extension of the original two year life of the committee to four years. Since the beginning, the committee has recommended the award of forty-four research grants, of which the largest was £371,000 for the establishment of the Enzyme Group at Oxford. The committee makes no apology for its decision to award five of the grants over periods as long as five years, because it considers that long term funding in suitable circumstances increases the possibility of recruiting really competent staff and encourages the full and unhindered development of new ideas. But several applications have been turned down because they did not involve sufficiently close collaboration between disciplines.

Although fourteen research studentships a year have been made available to the committee for distribution to its grantees, the review makes it clear that the chance of obtaining more training grants specifically for enzyme chemistry and technology is slim. But as industry begins to play a useful role (and the interest of Whatman Biochemicals in enzyme purification is a case in point) it should be possible to make more use of the SRC's Cooperative Awards in Pure Science. And workers in enzyme chemistry can still apply for the research studentships meted out by the Chemistry, Chemical Technology and Biology Committees of the SRC. Not surprisingly the committee is trying to encourage the teaching of enzyme mechanisms in university courses and it suggests that enzyme isolation, purification and reactions should form part of some undergraduate practical courses.

On research grants, the committee says that many aspects of the subject are still failing to attract sufficient grant applications. Enzyme isolation and the production of pure enzymes and cell abstracts are two examples. The SRC is already partially supporting the extension of facilities at the Microbiological Research Establishment, Porton, so that the availability of partially purified enzymes can be increased, but the committee is particularly keen to encourage more proposals for work on enzyme separation procedures, especially those involving chromatographic methods.

The structural study of enzymes was singled out in the original SRC panel report as an important feature of the continued development of enzyme chemistry and there seems to be no lack of suitable applications. Funds have been provided for a high field NMR spectrometer for the Oxford group and some instrument time will eventually be made available to others working on biological problems. The committee has also been consistently of the opinion that studies of peptide synthesis are essential to the understanding of enzyme mechanisms and the review calls for more fundamental work to be done; it cites the problems of the unambiguous formation of disulphide cross-linkages, the protection of histidine and the incorporation of tryptophan as worthy of further investigation.

The application of enzymes in industrial processes is still apparently a completely open field and it is impossible to say in what ways the unique reaction-mediating properties of enzymes will be used. The SRC has awarded grants to three groups working on the attachment of enzymes to solid supports (for example, a chromatographic column or a glass tube) and this kind of research could lead to the production of viable systems which use enzymes to catalyse chemical processes that are difficult to perform by conventional means.

METRICATION

Waiting for a Policy

The announcement (see page 439) that the United States Department of Commerce is recommending metrication to Congress may make some reluctant British companies finally decide to change to the metric system. Several companies which have been exporting their goods to the United States have so far resisted the British Metrication Board's entreaties to go metric, and this has been a major stumbling block to the process that was started in 1965. Very few countries have not so far either changed to the metric system or made a firm commitment to do so. The United States is, of course, the largest country that has not yet decided to change, and it keeps company with such bastions of the imperial system of measurement as Barbados, Burma, Gambia, Liberia, Muscat and Oman, Nauru, Sierra Leone, Southern Yemen, Tonga and Trinidad.

What progress has been achieved in Britain during the past six years? The aim was to convert British industry to the metric system by the end of 1975. The British Standards Institution, taking the construction industry as an example, reports that nearly all the companies involved with public contracts have already changed and that two thirds of the others have either changed or are scheduled to change. Elsewhere, most larger companies have made the change and the smaller and middle sized companies are thinking of following suit.

In Britain, there is as yet no legislation to compel change by 1975 or any other date. Moreover, the Metrication Board is required to work chiefly by exhortation. The original aim, decided by the British Standards Institution in collaboration with industry, was that 75 per cent of all companies in Britain should convert by 1975, and the institution reports that this will be achieved at the present rate; it even hopes that the final figure will be more like 85 per cent.

The advantages of metrication to industries involved in overseas trade are self-apparent, but what are not very clear are the advantages to industries that do not export. The British Standards Institution is finding that companies that have converted have saved a great deal of money in the metric rationalization process. The philosophy that the costs of metrication "lie where they fall" has not encouraged such companies to go metric, but the many examples of cost saving that are now becoming obvious, together with the realization that in the near future components made to imperial standards will cost more, are making many companies rethink their policy.

If the industrial sector is well on the way to its original aim, there is a serious delay in the public and educational sectors. The present government has not been over-enthusiastic about metrication but has not, on the other hand, made any decisions to alter course. A White Paper on metrication that will spell out the government's policy has been expected for some time, but it will not appear at least until Parliament returns after the summer recess. The original intention was to introduce metric road signs in 1973, but Mr John Peyton, Minister for Transport, announced in late 1970 that this will not now be the case and that the government has no alternative date in mind.

There is no doubt that a definite statement of government policy is needed to reassure educationists who are already heavily committed to metrication. After 1972, all school examinations will be set in metric units and the SI system of units will be universally accepted. Textbooks have also been rewritten to conform with these standards. If a change of government policy towards metrication in education is expressed in the White Paper it will, as a spokesman of the National Union of Teachers said this week, cause consternation.

BUILDING RESEARCH

Constructive Policies

The Building Research Station, now under entirely new management—at least in name—looks likely to spend almost £2½ million in the financial year 1970–71, according to the annual report (*Building Research Station 1970*, HMSO, 85p). The station, which is at Garston, Hertfordshire, and its Scottish Laboratory, now fully established in new quarters at East Kilbride, is the construction research arm of what used to be the Ministry of Public Building and Works. In the reorganization of central government last autumn, however, the BRS, in company with the Road Research Laboratory, came under the wing of the new Department of the Environment.

The BRS is chiefly concerned with research into environmental design—for example, sound insulation techniques, the design of safe buildings and ways of mechanizing their construction and the performance and improvement of building materials. All of these interests are well illustrated by the Finchampstead project where the construction of 172 houses was planned and analysed along BRS lines. One measure of the success of this project is the estimated 900 man-hours required for each dwelling. A recent survey has shown that 1,200 man-hours per house is a more usual figure. The BRS provides an advisory unit, established in May 1970, and of course the station is the technical agent for the Agrément Board which takes responsibility for the testing and approval of new building materials.

On the international front, the station has recently played an important part in the sale of a 5,000-tonne hydraulic press to the Yugoslavian Government. The press, worth about half a million pounds, was designed and built at Garston by a consortium of interests including the BRS called Go-Con Concrete Ltd and is used for the rapid production of large concrete panels. Finance for the construction of the press was arranged with the help of the National Research and Development Corporation.

ELECTRICITY SUPPLY

Computing the Future

Planning the development of an electricity supply system so that costs are kept to a minimum can no longer be carried on without a computer. Both the Central Electricity Generating Board in Britain and the Commission of the European Communities now make extensive use of computing methods to decide the optimum mix of the types of power plant at present available or expected to prove themselves before the end of the century.

When only coal-fired plant was available, planning entailed the solution of a classic problem in operational research—how to place a number of coal-users in such a way that the cost of transporting coal from the coalfield was minimized. But the evolution of oil-fired and nuclear plant and the increasing use of gas turbines for meeting peak demand have considerably complicated the problem. Planning now involves not only the estimation of the distribution of demand throughout the year but also the relative capital and running costs of different types of plant and some prediction of the way in which nuclear technology is likely to develop.

The approaches to the problem which have been adopted by the CEGB and the research group at the Joint Research Centre at Ispra (where the European research is being carried out) are somewhat different. Both aim to evolve a plan for the next thirty years or so which can be continually updated, but the work at Ispra takes more detailed account of the possible development of nuclear technology.

The whole problem is a system analyst's dream. The CEGB programme, for example, has been evolved over a period of about ten years and contains an expression for the total cost of electricity during a given year. The objective is to minimize this expression under the applied constraints such as government regulations about the use of capital and the cost and availability of fossil fuels.

Several factors have to be taken into account in setting up the expression for the cost. The total amount of generating capacity which must be available is, of course, determined by the peak demand even though this may last for only a few days and at first sight there is an obvious merit order for power plants which is bound to affect the distribution between the different types. Nuclear plants are the cheapest to run, followed by oil, coal and gas turbine. On the other hand, the order of capital costs is reversed; gas turbine plants are the cheapest and the capital cost of a nuclear station can be about fifty per cent higher than that of an oil-fired station of comparable capacity. The philosophy behind the programme is that the type of generator with the cheapest running cost should supply electricity for as much of the year as possible and that the more expensive forms of power generation should only be used to meet the higher power demands that occur for short periods of the year. As more and more of the plant with the cheaper running costs is introduced into the system, the more expensive and older plant can be run for shorter periods and eventually phased out. The CEGB programme has predicted the future power plant mix shown in the Table.

Generator Plant Mix predicted by the CEGB Programme

Year	Nuclear	Conventional
1975	13%	87%
1980	>20%	<80%
2000	60%	40%

Although the computer work at Ispra is along similar lines, it is in many ways more detailed. Among its predictions for the European electricity supply industry are that the amount of electricity generated by non-nuclear means will level off in 1985 but will increase again in 1995 when more capacity will be required to supply electricity in the peak periods. The use of fast reactors will increase at the maximum rate soon after their introduction (estimated to be in 1985) but after a further fifteen years or so, the growth rate will be determined chiefly by the rate of increase of the power demand. The progress made by the high temperature re-

SRC Members

The Science Research Council has announced the appointment of six new members to its research boards so as to make up for the regular retirement of previous members. On the **Astronomy Space and Radio Board,** Professor J. Ring (Imperial College, London) and Mr M. O. Robins (Ministry of Aviation Supply) replace Mr R. Lees (Ministry of Aviation Supply) and Professor P. A. Sheppard (Imperial College, London). On the **Engineering Board,** Professor G. D. S. MacLellan (University of Leicester), Professor R. J. A. Paul (University College of North Wales) and Professor R. W. H. Sargent (Imperial College, London) replace Professor J. G. Ball (Imperial College, London), Mr H. R. Galleymore (Procter & Gamble Limited) and Dr M. R. Gavin (Chelsea College of Science and Technology). On the **Nuclear Physics Board,** Professor R. G. Chambers (University of Bristol), Professor L. L. Green (University of Liverpool) and Dr K. F. Riley (University of Cambridge) replace Professor W. E. Burcham (University of Birmingham), Sir Derman Christopherson (University of Durham) and Dr K. Mather (University of Southampton). Dr T. Emmerson (Guest, Keen and Nettlefolds Limited) and Professor Sir Ronald Nyholm (University College, London) have retired from the **Science Board** but no new appointments have been made.

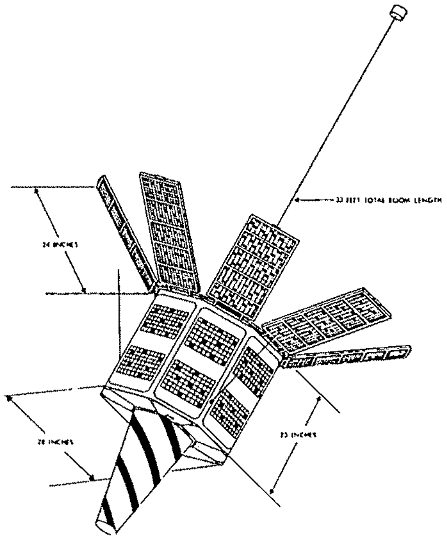
actors is expected to be determined almost entirely by comparisons with the fast breeder reactor during development and the installed capacity will not increase at all once the fast breeder reactor becomes established.

METEOROLOGY

Come in Please, No. 24

A weather satellite that obtains its data not from cameras but by the interrogation of automatic sensors carried into the atmosphere by balloons is to be launched next week. The balloons will take the sensors into a region which, because of its remoteness, is *terra incognita* on weather maps—the oceans of the southern hemisphere.

Although the satellite is experimental in the sense that the electronic system to be used for collecting data has not been applied before, the experiment is on a sufficiently large scale to make a significant contribution to the World Weather Programme. Five hundred sensors and balloons are available for launch from three locations in Argentina at latitudes of 33°, 39°, and 55° S by the French Centre Nationale d'Etudes Spatiales, which also developed the satellite to be launched on or after August 16 by NASA.



The French Eole weather satellite. The long boom is the gravity gradient stabilization system, so that the conical spiral antenna for balloon interrogation and data collection points towards the Earth.

In previous trials, balloons launched from southern hemisphere stations have lasted for several months, circumnavigating the Earth several times until lost because of icing. The French satellite carries a 4 Watt, 464 MHz transmitter for the interrogation of the balloon-borne sensors, a receiver for collecting the data transmitted by the sensors, and a 136 MHz transmitter for relaying the data to ground stations.

The philosophy of the experiment seems to be the recognition that in spite of the impact that pictures of cloud cover from conventional weather satellites have had on weather analysis and forecasting, there is still an urgent need for more measurements of temperature, pressure and wind speed which ground stations provide. In the absence of a technique that allows pressures and wind speeds in the lower atmosphere to be measured directly from sensors on satellites, the approach being tried by CNES and NASA is the most promising way of obtaining data from remote areas that are of meteorological interest.

Although the techniques of communications satellites have been used before for the collection of data from automatic sensors, the French system is an important advance on earlier American experiments because of its large capacity, allowing the tracking of as many as 500 balloons. It will be possible to determine the horizontal location of the balloons to the nearest 3 km (their vertical position will be governed by their inflation pressure so that they float at 11.85 km), a considerable improvement on a similar data collection system that has been tested on the Nimbus satellites and better by far than tracking from the ground.

EASTERN SCIENCE

Comecon Looks Ahead

from our Soviet Correspondent

The new "complex programme" of economic integration of the COMECON countries, promulgated by the 25th session of COMECON, raises some interesting questions about the future of science and technology in eastern Europe. This programme, which will be implemented during the next 15–20 years, is aimed at the "further deepening and improvement of economic co-operation and the development of the socialist economic integration of the member countries of COMECON" by measures including a "collective currency policy", the sharing of research and development experience between the member countries, a common policy of external trade, and a coordinated plan for basic research and industry. This, however, is to be accomplished on a basis of "respect for national sovereignty, independence and national interests, non-interference in the internal affairs of member countries, complete equality of rights, mutual advantage and comradely cooperation". The programme will be based on "multilateral and bilateral mutual consultations", and will not be accompanied by the creation of new "supranational bodies".

This stress on national autonomy within COMECON seems to have been largely at the insistence of the Romanian delegation, which has been active in resisting what would appear to be the logical outcome of COMECON — virtual integration of the eastern bloc with the Soviet Union. But it seems unlikely that this view will stand up against the implicit supranational nature of the projects proposed by the programme. These include, in particular, the "planned expansion of international specialization and cooperation in industry, science and technology", the end result of which, whether decided by a supranational body, or by "direct links between the ministries and other state organs concerned", will be, to some extent, a curtailment of national autonomy as far as the choice of project is concerned.

A large section of the programme deals specifically with cooperation in science and technology. The emphasis here is on matters of policy, such as the planning and solution of important scientific and technical problems, cooperation in research and the interchange of information on research and development and mutual training programmes. The list of basic problems to be tackled using the "most effective forms of mutual cooperation" is long and somewhat vague in its terms, but seems to concentrate mainly on biology and biophysics, with special reference to agriculture and food production, mechanization, automation and computers, more efficient use of natural resources, including marine resources (the Pacific Ocean is especially mentioned, in a manner almost suggesting that it is a private preserve of COMECON), semi-conductors, and the demands of metallurgy and industry in general.

Much attention is given to the "organizational forms and legal principles" of the proposed cooperation, but no concrete projects are indicated. Information exchange is greatly emphasized, and, on the basis of the existing COMECON International Centre of Scientific and Technical Information in Moscow, a system of information exchange will be set up during 1972–73. The production of scientific instruments and apparatus will be one of the first fields to be reorganized and, during the next year, proposals are to be worked out by the member countries on the establishment of international societies for the production of high-precision instruments (including apparatus for nuclear research) and the establishment of a coordinating centre for cooperation on biomedical and clinical research equipment. Production of research materials is also to be integrated, including materials for optical spectroscopy, experimental physiology and high vacuum work.

Although the programme speaks throughout of the "member countries" and the "interested countries" involved in the various cooperative projects, it is inevitable that the Soviet Union will play the leading part in the planning. Although a COMECON scientific centre has sometimes been established outside the Soviet Union (Weed and Pest Control at Poznań, Timber Research at Bratislava), the location of the Information Centre in Moscow will tend to orientate all major planning towards Moscow.

EUROPEAN RESEARCH

Aigrain Projects Persist

Plans have now been laid for a Pan-European conference on scientific and technical research in Brussels in November. The initiative comes from the Commission of the European Communities, and in particular from the technical working groups under Mr Pierre Aigrain which have in the past two years sought to define the fields in which European countries might collaborate on scientific and technical projects. At a meeting in Brussels at the end of July, representatives of nineteen countries in Europe picked out a number of particular problems from the shopping list which has been accumulating since 1969. The intention is that there should be a conference in the second half of September to settle questions such as the organization and financing of joint research projects, and that the conference of ministers in November should then set up a series of specific collaborative projects on which work could begin immediately.

According to an announcement in Brussels, the original list of proposals has been narrowed down—a term which must be understood to include selection as well as refinement—to a number of specific issues. It has, for example, been decided that the most tangible way of making progress in collaborative data processing is to set up a European Data Transmission Network and then a program library. This, as it happens, is a project developed by the staff of the European Communities on the instructions of the Hague Conference on technical collaboration in September 1969. It is now proposed that the collaboration of European states should be invited in long-term studies of passenger transport, what are called "various means of combating nuisances", a term now understood to include not merely the properties of sulphur in the atmosphere but the treatment of mud and other solid waste. A newish departure is a series of projects in metallurgical research. There is talk of collaboration on radio wave propagation.

One striking property of the shopping list now current is the disappearance of some of the more ambitious projects such as the scheme for the development of a large computer. This, as it has turned out, is at once such a risky venture and one that promises such large commercial gain that the companies able to make a contribution to the project have preferred to get together among themselves and—prudently—to enlist American interest as well. Similarly, the original proposal for collaborative research in telecommunications is conspicuous by its absence—nobody pretends that Europe has too much good work of this kind, but it is clear that there are too many companies in Europe who think of themselves, perhaps with justice, as potential competitors of AT&T for collaboration to be easy at this stage. And, of course, from the beginning of these discussions about the future of European collaboration on technical developments, it has been assumed that, having burned its fingers with Euratom, the European Community would not for the time being be able to turn its attention to fostering collaboration in the development of nuclear reactors. That is a stable door that nobody has the courage to shut even if the horse has not yet bolted.

HOVERCRAFT

How Fast for Hovertrain?

With the delivery this week from Vickers's Swindon factory of the first full-scale British tracked hovercraft, a new phase in the British development of this novel type of high speed surface travel is initiated. So far, the building programme of government-financed Tracked Hovercraft Limited (THL) at Cambridge has taken rather longer than scheduled for contractors to build a preliminary three miles of elevated box-beam track along the bank of a disused seventeenth century canal on the nearby Fens. In parallel, at the Cambridge laboratory, a variety of scale trials and studies of fundamental design features of the proposed vehicle have taken place, particularly concentrating on the specially developed single-sided linear electric motor for propulsion and the characteristics of the table-top sized hoverpads that will provide both lift and guidance.

The newly delivered 75 foot car is being equipped at a trackside workshop at the Erith terminal of the test monorail. All the interior equipment, the hoverpads and the linear motor installation are being handled by THL staff. The fitting out is expected to take some two months. The craft will then weigh 51 tons. Trials on track will then start. In view of the short length so far completed, the RTV3L vehicle is not intended to exceed 150 m.p.h. this year though rated for 300 m.p.h. (450 k.p.h.). The hope is to extend the track to five or eight miles next year when speeds up to 250 m.p.h. can be attempted. The craft will travel without a driver or passengers during the trials period. It is more efficient to control it electronically from the trackside and to use the interior space for every conceivable instrumentation so that no feature of "ride", vibration, acceleration, braking and so forth goes unrecorded.

There is one question to be answered: having received delivery of a 300 m.p.h. vehicle, is THL going to be able to exploit it? It seems to depend on a further subvention from government for extending the track to at least eight miles: eighteen were originally in view. The £3½ million initial investment is not yet exhausted, but by the end of 1971 the need of further investment will be becoming urgent. So far the government has studiously avoided committing itself in any way.

NEW WORLD

Metric Standards Round the Corner

The National Bureau of Standards has predictably recommended that the United States should switch over to a metric system of measurement in the course of the next decade. In the report of the US Metric Study, which has occupied the bureau since the passing of the Metric Study Act by Congress in August 1968, the principal theme is that the metric system is for practical purposes unavoidable. "Eventually the United States will join the rest of the world in the use of the metric system as the predominant common language of measurement." But even the adoption of externally designed units of measurement may become a patriotic challenge. "Americans working cooperatively can resolve this question once and for all."

The report of the Metric Study has the inelegant title *A Metric America: A Decision whose Time has Come* (US Government Printing Office, $2.50). The supporting evidence presented at the hearings of the study group has been published separately in twelve volumes. Responsibility for the study, originally placed with the Department of Commerce by Congress, has been delegated to the National Bureau of Standards but the Secretary of Commerce has also received advice from a large representative committee. Most of the evidence on which the report is based was collected during the summer of 1970 at public meetings which lasted altogether twenty days.

It remains to be seen what Congress will make of the report on metrication and of the argument that metrication is historically necessary. Congress failed to respond to Jefferson's commendation of the metric system as long ago as 1790, even before the definition of the metre. Since then, Congress has built up a long record of flirtation with bits and pieces of the metric system, especially at the turn of the century. Most recently, the United States seems to have been prodded into action partly by the National Bureau of Standards itself and partly by the spectacular example of countries such as Britain which have astonished not merely the tourists but themselves in their conversion to the metric cause.

The report of the study group says that the deliberate encouragement of the tendency towards metric could quite quickly create a situation in which the metric system was as widely used as the conventional system in the United States. Schools, it says, should emphasize metric measurements. Industries could be persuaded to conversion before they were forced by circumstances to measure metrically, and public authorities responsible for traffic signs and the like should seize their opportunities to make a captive audience think in kilometres.

In the same spirit of gradualism, and with some regrettable signs of falling for the confusion between units of measurement and standardization of sizes, the committee seeks to comfort anxious Americans by pointing out that it will never be necessary to change the size of an American football field or to alter the gauge of the great railroads (which may in any case be out of business before metric ways are adopted in the United States).

But what will the United States gain from such a development? The study group points out that agreements such as that between the United Kingdom, Germany and France on metric electronics arts, themselves the prototypes of more ambitious agreements yet to be negotiated, could exclude many American products from important markets. The study group has even calculated that American exports likely to be at risk in this sense in 1969 accounted for $14,000 million and that an American failure to move towards the metric system will mean that something like $600 million worth of exports will be unsold in 1975.

The Metric Study report points out that the compatibility of United States standards with those of other countries, particularly in Europe, may be particularly important at a time when the United States share of world trade is diminishing steadily—it fell by more than ten per cent during the sixties—and when arrangements such as the European Economic Community will provide further deterrents to American exports. Multi-national corporations are yet another source of pressure towards metrication.

The study group's enquiries among industrial companies seem fully to support its conclusions. In a sample of 4,000 companies chosen to represent American industry as a whole, those for the metric system represent a majority of the labour force, with larger companies more anxious to switch over. As a whole, 70 per cent of the labour force seems to be employed by manufacturers anxious to make the change. Among the general public, the study group's chief discovery seems to be that ignorance is the most common condition—only 40 per cent of the respondents to a social survey were able to name a single metric unit. In industry and among the public as a whole, however, it seems to be accepted that if there is to be a change, it should be planned as a coordinated operation and spread over the next ten years.

With this starting point, the study group urges that there should be a coordinating organization to superintend the changeover. The study group has also singled out two points at which an early start could be made on adaptation to the future—closer participation in the making of international standards and the incorporation of metric measurements into school curricula. In the long run, there will have to be special studies of particular problems such as that already being undertaken by the Industrial Fasteners Institute on the definition of metric thread sizes. Eventually, there will also have to be some decisions about the extent to which collaboration between manufacturers on the development of metric standards can be freed from the threat of anti-trust prosecution. The study group has also committed itself to a complicated cost-benefit analysis of the transition to metric. It assumes, conservatively perhaps, that the benefit of an extra $600 million a year on the balance of trade is more than $1,000 million for the economy as a whole. Moreover, the study group points out that there would be a number of important economies arising from the way in which the transition to a metric system would provide opportunities for simplifying present practice and, for example, for reducing the numbers of standard items of equipment such as screw thread sizes. The cost of the transition, for manufacturing industry, is estimated to be between $6,000 million and $40,000 million spread over ten years. In general, therefore, the committee suggests that the costs are unlikely to be much greater than the benefits.

Whether the report now published will finally tip the scales in the United States in favour of conversion to metric may be an open question, but there is no doubt that the report will do a good deal for the moral of the Metrication Board in the United Kingdom, recently much cast down by the apparent indifference of the Conservative Government. Indeed, the working group declares that the British metrication programme should be regarded as a pilot for the conversion in the United States. Lord Ritchie-Calder, chairman of the Metrication Board, will no doubt be reminded once more that prophets are not highly regarded in their own countries.

NEWS AND VIEWS

The Universe Considered as Hole

DURING the past few years, astronomers have gained an insight into black holes (or collapsars) which has made the study of these phenomena an increasingly important part of astronomy. This field of research was once largely the preserve of mathematicians concerned with the nature of space-time in an abstract way; observational developments now suggest, however, that collapsars play a vital part in the evolution of stars, galaxies, and the Universe as a whole. The latest calculations pointing to the possible importance of collapsars in binary systems appear in this issue of *Nature* (page 465). G. W. Gibbons and S. W. Hawking have followed up the line of investigation pointed to by Trimble and Thorne (*Astrophys. J.*, **156**, 1013; 1969) and conclude, from a study of the properties of seven systems shown to be binary stars by the Doppler motion of lines in their spectra, that there is suggestive evidence for the presence of black holes in some binaries. This must also lend weight to the contention made by Cameron and supported by Stothers that there is a collapsar in the system ε Aurigae (*Nature*, **229**, 178 and 180; 1971).

But what exactly is a collapsar? The general scientific imagination may well be captured by this concept of a "hole in space", but all too often it is felt that, because the prediction of this effect stems from Einstein's general theory of relativity, an understanding of it requires specialized mathematical knowledge. This is far from the truth. Like many of the fruits of this elegant theory the prediction, once made, can easily be understood in physical terms. Any star with more than 1.4 solar masses left when it has exhausted its nuclear fuel cannot support itself against gravitational collapse. The pressure at the centre of the cold star becomes so great that the fundamental nuclear forces are overcome, and matter is compressed beyond the density of atomic nuclei. This process is self sustaining, because such compression results in a higher density, a stronger gravitational field, and thus still more rapid collapse. Eventually, the collapsar has the properties of a point source of infinitely dense material. Curious as this is, it is the effect of the gravitational field produced on the space outside the collapsar which is responsible for the current wave of interest in black holes.

Within a critical radius (the particle horizon), the field is so intense that no matter, nor any radiation, can escape from the collapsar, although material can continue to be absorbed from the Universe. Hence the name black hole —the only way in which these objects can be detected is by their gravitational fields. This has great appeal to cosmologists, many of whom believe that there should be more matter in the Universe than can be seen in the form of bright galaxies. It also opens the way to intriguing mathematical games concerned with the possibility of extracting energy from these sources.

The most extravagant suggestion is that matter swallowed up by black holes re-emerges into the Universe from white holes, which lie at the centres of active galaxies and quasars. This could ensure the overall conservation of mass/energy while offering some explanation of the extremely violent events observed in some astronomical objects. At a more sophisticated level, it seems that energy could be extracted from the immediate vicinity of a collapsar by the break up of another object passing nearby. During a conference held from July 19 to 21 at the Institute of Theoretical Astronomy in Cambridge, which will shortly be reported in *Nature*, there was discussion of the properties of the ergosphere, a region just outside the particle horizon. A mass passing through this region can break up under certain conditions in such a way that one fragment falls into the black hole while the other is accelerated, gaining energy in the same way that the proposed grand tour space probes will gain energy from the rotational energy of the giant planets—a slingshot effect. But the escaping fragment can gain so much kinetic energy that it leaves the region of the collapsar with more mass/energy than that of the entire incident mass.

This mechanism must unfortunately remain a toy for the mathematicians, because the collapsars required to explain the activity of many observed galactic nuclei in terms of this effect would be implausibly large. For the present, however, practical astronomers and physicists would prefer to seek some other energizing process for these active galaxies and quasars. Black holes need not, however, be quite so extremely violent as this conventional picture conjures up. To be sure, objects like stars can only disappear inside their own particle horizons when compressed to very great densities. But while the mass of a sphere of matter at some uniform density varies as the cube of the sphere's radius, the gravitational force falls off only as r^2. For any density chosen there is some critical mass above which the sphere is within its particle horizon, or, alternatively, for any mass there is some critical density for which this occurs, and the greater the mass chosen the smaller is the required critical density. So although gravity is a weak force, its action over very great distances implies that a reasonably dense galaxy —that is, one with a density comparable to the density of some stellar clusters in our galaxy—could contain enough mass to prevent the escape of matter or radiation from its immediate vicinity.

Once again, the cosmologists who wish for more matter in the Universe are delighted—now, it seems, whole galaxies can be hidden in black holes. But why do the cosmologists want yet more matter in the visible galaxies? In short, it is to provide enough mass for the Universe to be closed. This would solve many problems regarding the nature and origin of the Universe, and would fit many of the observations of distant sources made at radio, optical and other wavelengths. But if the Universe is closed—the finite, yet unbounded three-dimensional analogue of the surface of a sphere—then the world is in essentially a rather large black hole. The corollary to this is that the expansion of the Universe must ultimately be reversed, eventually producing a compression to densities where present understanding of physics breaks down, with, perhaps, a further expansion from the primaeval matter in a cycle of pulsations which had no beginning and will have no end.

Significance of Sex Linked Antigens

THE observation that individuals of the same species may differ from each other antigenically is now so well established as to hardly bear remarking. Antigen hunting, the identification of more and more antigens, has rightly fallen into disrepute as a worthwhile activity, yet it cannot be claimed that there is any clear idea of the biological significance of the remarkable antigenic variation observed in most mammalian species.

Two extreme views for this variation can be put forward. The first is that it arises as a result of a random event, mutation, but that one form of the antigenic material confers some kind of biological advantage, and the alternative form confers another kind of advantage. Antigenic variation, as pointed out by E. B. Ford, would thus form an example of a balanced polymorphism, and takes its place with such phenomena as variation in rings on snail shells and spots on insect wings as part of a more or less homogeneous group of biological variations. On this hypothesis there is a need to look only for a cause for the maintenance of the antigenic variation, and it may be fortuitous that the variant materials are antigenic. They have a role in the cell membrane, and one antigenic form may be more advantageous in one environment than in another.

The alternative hypothesis is that it is the antigenicity of the materials which is important. There have been many hypotheses that have utilized this idea—one of the most recent is the suggestion of Jerne (*Europ. J. Immunol.*, **1**, 1; 1971) that histocompatibility antigens, such as H-2 antigens in the mouse, may play a part in the generation of immunoglobulin diversity. It has also been frequently suggested that histocompatibility antigens play a part in distinguishing neoplastic cells from normal cells, although the way in which this is done is far from clear.

These two kinds of hypothesis can, of course, be merged into one, because all variation must originate in mutation, and it can hardly be the case, for example, that the need to distinguish neoplastic and normal cells gave rise to antigenic variation—the origin of any variation must precede its utilization.

Even if this view of the origin of variation is accepted, it is still necessary to look for the reason for its survival, that is, for its "function". The direct demonstration of the mouse H-Y antigen, controlled by a gene on the *Y* chromosome, on mouse spermatozoa by Goldberg, Boyse, Bennett, Scheid and Carswell (see page 478 of this issue of *Nature*) puts this antigen firmly on the map as an antigenic system the biological role of which ought to be investigated. The use of skin grafts to investigate the H-Y antigen has hitherto clearly limited what could be done.

If it is acknowledged that antigen systems like H-Y in the mouse, and the human Xg^a blood group antigen (controlled by an *X* chromosome gene), may have biological roles, why are the genes that control them on the *X* or *Y* chromosomes? The same question can, of course, be asked of other genes present in moderately high frequency in the population, such as those on the human *X* chromosome which affect colour vision. One should not, perhaps, make too much of this—the *X* and *Y* chromosomes represent a considerable proportion of the animal's genetic material; that it can all be concerned with sexual differentiation seems unlikely.

Apart from these rather vague speculations, it is much easier to comment on the usefulness of these antigens to investigators. Race and Sanger, in their book *Blood Groups in Man* (Blackwell, Oxford and Edinburgh, 1968), point out how the investigation of the Xg^a blood group has revolutionized knowledge of the human *X* chromosome linkage group, and indeed of human genetics as a whole. The development of a direct cytotoxic test for the mouse H-Y antigen by Goldberg *et al.* could do the same for the mouse. Although many of the investigational problems which beset human genetics do not exist in the mouse, the development of a serological test will be a great spur to the investigation of the mouse *Y* linkage group, and it might one day lead to an answer to the question posed earlier—whether or not the H-Y gene is present on the *Y* chromosome fortuitously.

It is worthwhile drawing attention to another specific feature of Goldberg's work, that at least some, and therefore possibly all, *X* bearing spermatozoa carry the Y antigen and thus reflect the antigenic constitution of their precursor cells rather than the capabilities of the genetic material contained in the sperm; similar observations have now been made on several antigenic systems in spermatozoa. This therefore precludes the use of an immunological method, with any antigen system so far discovered, of either distinguishing or separating *X* or *Y* bearing spermatozoa, and is unlikely to form the basis of a technique for deliberate selection of male or female offspring.

DNA REPLICATION

Selective Inhibition

from our Cell Biology Correspondent

THE substituted uracil derivative, 6(p-hydroxyphenylazo)-uracil (HPUra) is today unlikely to be found outside the laboratory of N. C. Brown in Baltimore, who since 1966 has diligently been investigating its effects on DNA synthesis and DNA replication in a variety of bacteria. But to judge from what he has to say in the *Journal of Molecular Biology* (**59**, 1; 1971), the manufacturers of this compound, Imperial Chemical Industries Limited, can anticipate a spate of begging letters. For, according to Brown, HPUra inhibits the semiconservative replication of DNA without affecting DNA repair.

During the past five years Brown has shown that although the compound selectively and reversibly inhibits DNA replication in *Bacillus subtilis* and a range of Gram positive bacteria it does not bind with great affinity to DNA, it does not stop the replication of phage in *B. subtilis*, neither does it impair transcription, translation or the synthesis of bacterial cell wall materials. Attempts to characterize the way in which the drug acts by adding it to a range of membrane fractions, preparations of *B. subtilis* exposed to lysozyme and apparently even cells made permeable by exposure to toluene, have all failed. The DNA synthesis which these systems support *in vitro*, like the replication of phage (Brown, *Proc. US Nat. Acad. Sci.*, **67**, 1454; 1971), is refractory to HPUra.

Because of this Brown was forced to re-examine the effects of this compound on intact bacteria because they alone support the DNA replication process sensitive to HPUra. He selected the strain of *B. subtilis* 168 *thy*$^-$ *ind*$^-$ for this work, for as Pettijohn and Hanawalt have shown, cells of this strain, after exposure to ultraviolet irradiation, support extensive DNA repair synthesis and they therefore offer an opportunity of comparing the effects of HPUra on repair and replication. In an elegant series of experiments Brown has shown that although the semiconservative replication of the chromosome of this strain is blocked by HPUra, the repair of DNA damage caused by the ultraviolet irradiation continues unabated. For example, he labelled the DNA made after irradiation and in the presence of the drug with radioactive bromo-deoxyuridine and then analysed it on caesium chloride and alkaline gradients. The bulk of the labelled DNA turned up in short chains covalently linked to the parental DNA. Moreover the synthesis of this DNA was greatest in cells given the highest doses of irradiation, and it was inhibited by inhibitors of excision repair synthesis such as actinomycin D.

Because Brown found last year that the replication of virulent phages in *B. subtilis* is not blocked by HPUra he was at pains to eliminate the possibility that the synthesis of DNA in irradiated cells, which is insensitive to HPUra, is nothing more than the replication of a defective prophage induced by the irradiation. The properties of defective *B. subtilis* prophages make this idea implausible and furthermore he has shown, first, that synthesis of DNA in irradiated cells does not immediately depend on protein synthesis and, second, that mitomycin C treatment, which like irradiation induces defective prophages of *B. subtilis*, does not induce an HPUra-refractory DNA synthesis. In short, there seems little doubt that it is the repair of irradiation damage that continues in the presence of HPUra.

If HPUra is as selective an inhibitor of DNA semiconservative replication as Brown's work indicates it should prove an extremely useful tool for identifying the real DNA replicase. But Brown's claim that DNA synthesis in toluenized cells continues in the presence of this drug (and unfortunately he has not yet published the detailed evidence on which he rests this assertion) must come as a blow to cell biologists who have pinned their hopes on toluenized cells as a system for investigating DNA replication *in vitro*. The experiments reported by Sueoka's group in *Nature New Biology* (**232**, 111; 1971), for example, certainly suggest that toluenized *B. subtilis* cells support DNA replication rather than repair synthesis, but Brown's findings raise new doubts about that. If Brown is right, toluenized cells may have to be added to the scrap heap of bacterial preparations which, although they make DNA *in vitro*, do not support chromosomal replication identical to that occurring in intact cells.

ANTIQUITIES

Fooling the Experts

from our Archaeology Correspondent

NEW thermoluminescence work on supposedly ancient ceramic objects, all recently acquired by museums and collectors, shows how successfully forgers and fakers are taking in their clients. Two studies undertaken at the Research Laboratory for Archaeology and the History of Art at the University of Oxford indicate not only the effectiveness of the thermoluminescence method, but the great difficulty that experts have in distinguishing genuine objects from false ones simply by their appearance.

The first study, by M. J. Aitken, P. R. S. Moorey and P. J. Ucko (*Archaeometry*, **13**, 89; 1971), exposes as fakes no fewer than forty-eight out of sixty-six bowls, figurines and anthropomorphic vessels, which have supposedly come from illicit excavations at the prehistoric site of Hacilar in Turkey. Since the successful excavations there by James Mellaart in 1957 and subsequent years (*Excavations at Hacilar*, I and II: Edinburgh Univ. Press; 1970), the attractively painted pottery and baked clay figurines discovered have rightly had an important place in the early history of art. Similar objects from illicit excavations have fetched up to £3,000 on the antiquities market.

Thermoluminescence glow curves obtained by Aitken show that most of the specimens examined emitted very little light on heating. The thermoluminescence observed is proportional to the radiation which the clay has undergone since it was fired—the radiation originates chiefly from radioactive isotopes in the clay or in the soil in which the object was buried—and hence upon its age since firing. Forty-eight out of sixty-six objects were evidently recently fired. The remote possibility that genuine ancient pieces had undergone heating in recent times to consolidate them, thereby removing the accumulated thermoluminescence, was checked by S. J. Fleming and D. Stone-

Streptovaricins Suppress Oncogenicity

LAST March Brockman and his colleagues reported in *Nature* (**230**, 249; 1971) that the streptovaricins—a family of antibiotics, the structure of which is similar to that of the rifamycins—inhibit the activity of reverse transcriptase in mouse leukaemia virus particles. At concentrations of 40 μg/ml. the enzyme's activity was inhibited by 75 per cent. In next Wednesday's *Nature New Biology* Brockman's group describe their latest experiments with these drugs which show that streptovaricins not only inhibit the transformation by mouse sarcoma virus of mouse 3T3 cells growing in culture, but also selectively inhibit the progress of erythroblastic leukaemia and spleen enlargement induced in mice by Rauscher leukaemia virus. Their work thus suggests that streptovaricins might become useful chemotherapeutic agents for the treatment of cancer.

At concentrations which do not slow down the rate of cell division, those streptovaricins which inhibit reverse transcriptase also block by from 25 to 50 per cent the induction of foci of transformed cells by mouse sarcoma virus. This fact, together with the finding that the antibiotics are ineffective 24 h after infection, suggests that the inhibition of transformation results from the inhibition of reverse transcriptase activity. Moreover the inhibition of transformation by streptovaricins was enhanced if the cells were exposed simultaneously to interferon, which Brockman *et al.* suggest specifically inhibits the translation of viral messenger RNAs.

But inhibiting transformation *in vitro* is one thing; inhibiting the induction of a cancer in an intact animal is another. Can streptovaricin alter the course of events after mice are infected with a virus such as Rauscher leukaemia virus? According to Brockman and his colleagues it can. They find that mice fed streptovaricin in their food such that the concentration of the drug in their serum is from 1 to 3 μg/ml. are protected to a significant extent against splenomegaly induced by Rauscher murine leukaemia virus. The spleens of mice fed the drug before and throughout the infection are only about 50 per cent as large as those of mice given the virus but not the drug. Moreover when the drug is not given until 8 days after infection, when spleen enlargement is well under way, it can still significantly reduce further enlargement.

These findings, together with the observation that streptovaricin does not inhibit transformation *in vitro* if it is given 24 h after infection, lead Brockman's group to conclude that *in vivo* the drug is blocking secondary focus formation in the spleen. The drug does not, however, reduce the proliferation of normal haematopoietic cells, as judged by spleen focus counts, neither does it impair spleen enlargement in mice inoculated with the L1210 transplantable lymphoma cells.

In short, in mice the streptovaricins seem to block a virus-induced oncogenetic event rather than affecting the proliferation of malignant cells. In the intact animal it may therefore be acting as an inhibitor of tumour virus reverse transcriptase.

ham. They used the "pre-dose" technique, which depends on the enhanced susceptibility, after heating, to artificial irradiation shown by specimens which have previously had a radiation dose. Most of the samples with negligible initial thermoluminescence showed a small increase in susceptibility to irradiation after simulated re-firing, which suggests that they never had experienced the appreciable dose of radiation received over 7,000 years, in the normal course of things, by the genuine antiquities.

The second investigation, by S. J. Fleming, H. Jucker and J. Reiderer (*ibid.*, **13**, 143; 1971), reveals that most or all of the Etruscan wall paintings on terracotta recently on the Swiss and American art markets are very palpable fakes. The museums owning these painted slabs will have paid anything up to £10,000 each for them. Fleming *et al.* used both the fine grain and the inclusion thermoluminescence methods—the inclusion method utilizes the large quartz and other mineral grains present as inclusions in the clay—and a comparison of the results shows that the painted plaques were made some time during the past twelve years.

The layman, of course, always derives a little innocent pleasure from seeing the experts fooled—a pleasure which will not be shared by the museums in Bern, Basel and Munich owning "Etruscan" terracottas, or by the custodians of the Hacilar material around the world. A more serious consequence of such faking activities is brought out in Ucko's discussion. The fakes include a number of variants and ostensibly new types accepted, until now, as genuine by most authorities. Indeed the abundance of new "finds" on the market led Mellaart to propose that looters had discovered the hitherto unknown cemetery at Hacilar, unearthing vases which "probably were used only in ritual functions in shrines and graves". Ucko now suggests that the few genuine pieces could all have come from illicit digging in the settlement itself, so that the whole interpretation of the meaning and function of such genuine pieces as remain becomes very different.

It is a sobering thought too that, for most materials other than baked clay, no method as reliable as thermoluminescence exists for detecting fakes. Luristan bronzes and Cycladic marble figurines are but two more of the fields where collectors and museums have been consistently and profitably defrauded. There are far more of them in the museums of the world than ever were excavated. The obvious moral is that museums should be less eager to encourage illicit excavation by paying large sums for unprovenanced antiquities. By doing so they are supporting, often very generously, looters and fakers alike.

BEHAVIOUR

Displays Analysed

from our Animal Behaviour Correspondent

THE most striking aspects of an animal's behavioural repertoire are often the "displays" it gives in sexual or aggressive encounters. Much is now known about the behaviours which birds and fish show during courtship and aggression, and there has been much speculation as to the underlying physiological mechanisms which give rise to these conspicuous displays. Elements of displays of animals, and sometimes whole behavioural sequences, can now be produced by electrical stimulation of the brain or by injection of hormones. The idea that such displays might be a particularly fruitful meeting ground for ethology and physiology prompted the meeting of the Association for the Study of Animal Behaviour at the University of Sussex from July 26 to 29. As Professor R. J. Andrew (University of Sussex) pointed out, displays have been selected during evolution to provide an accurate "read out" of an animal's internal state to another animal, and so may well be able to do so for the human observer.

The meeting provided an excellent opportunity for the exchange of ideas, but it soon became clear that there is still a long way to go before the physiology of even the most commonly observed displays is elucidated. There were several reports of researches into the role of various brain structures in controlling behaviour, but the precise function of these areas and their interrelations with other parts of the brain are still obscure, possibly because the

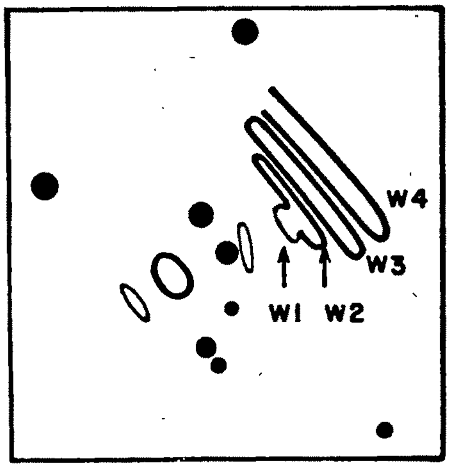
Exploding Magnetosphere May Cause Crab Glitches

BEFORE detailed timings of the Crab pulsar became available, astronomers were concerned to explain the amazing regularity of pulsar pulses. But now it is the small irregularities that have been revealed in the periodicity of the Crab pulsar for which explanations are being sought, in terms of the view that pulsars are rapidly spinning neutron stars which provides a satisfactory explanation of the gross features of pulsars. A review of the considerable data now available on the irregularities of the Crab pulsar—the largest and most sudden of which are called glitches, although an entire spectrum of events of different magnitudes and time scales can occur—is given by Jeffrey Scargle of Lick Observatory and Franco Pacini of the Laboratorio di Astrofisica at Frascati (Italy) in next Monday's *Nature Physical Science*.

The popular view that the irregularities are caused by what are called "starquakes" in a solid outer crust surrounding the neutron superfluid core of a neutron star does not find favour with Scargle and Pacini. Although changes in the internal structure of a neutron star, such as a starquake, would lead to an alteration in the moment of inertia of the spinning star that would be reflected in a change in the periodicity of the pulses, Scargle and Pacini point out that this notion is unsatisfactory on energy considerations.

The reason is that some filamentary concentrations of gas adjacent to the Crab pulsar seem to move in tune with the glitches, requiring more energy than can be provided by the starquake explanation. As an alternative explanation Scargle and Pacini suggest that the gas is excited from time to time by the sudden release of plasma from the magnetosphere of the pulsar, which would also lead to changes in the dynamics of the spinning pulsar that would be reflected in the pulse periodicity.

These occasional outbursts supplement the continuous injection of energy into the Crab Nebula by the escape of particles from the pulsar along open field lines. Much work needs to be done to investigate the kinds of plasma instabilities that can occur in the magnetospheres of neutron stars, but on the face of it this model seems to be a neat way of accounting for several features of the Crab pulsar.



The Crab pulsar, at the centre of this diagram, seems to be associated with a series of wisps of gas, W1, W2, W3 and W4. According to the review by Scargle and Pacini, Wisps 4, 3 and 2 seem to have been generated from Wisp 1, possibly as a result of the activation of Wisp 1 by the explosive release of plasma from the magnetosphere of the pulsar. The impact of this plasma pushes Wisp 1 out from the pulsar until the pressure is balanced by the pressure of the plasma and magnetic field of the Crab Nebula. Wisps 2, 3 and 4 have been generated by the magnetosonic waves which this motion of Wisp 1 produces.

brain, like a computer, can be "programmed" to do different jobs at different times. Indeed, the animal-computer analogy was heard more than once, from Dr J. D. Delius (University of Durham) and also from Dr D. J. McFarland (University of Oxford) who argued that animals allocate their time between different behaviours by "time sharing".

Physiological interpretation of a behaviour pattern is facilitated by an accurate description of the phenomenon to be explained, so that methods of recording and analysing behaviour are extremely important. Dr U. Weidmann (University of Leicester) illustrated his technique of frame-by-frame film analysis of the displays of mallard ducks as a method of discovering spatial and temporal relations between the birds that would be impossible by more conventional means. Dr P. Slater (University of Sussex) talked of the difficulties of describing and making sense of complex sequences of behaviour, and Drs R. Dawkins and M. Dawkins (University of Oxford) presented some methods of describing and predicting moment to moment changes in the fine structure of a behavioural act.

Better methods of description and the application of statistical techniques to uncover underlying patterns may well prove as useful a method for gaining an understanding of what goes on inside an animal as the already fruitful physiological approaches.

PROTEINS

Oxidation to Order

from our Molecular Biology Correspondent

A GROUP at the University of Padua, Jori, Scoffone and their colleagues, have cornered the market in photo-oxidation of proteins. By a series of chemical subterfuges they have shown how the scope and precision of the method can be extended to make it potentially one of the most useful resources of the protein chemist. In their latest article (on papain) they present a striking demonstration of the delicate molecular surgery that is now feasible (Jori *et al.*, *J. Mol. Biol.*, **59**, 151; 1971).

Papain contains a single thiol group, which is a part of the active site, and is readily modified. A suitable chromophoric group attached to it can then be used as a sensitizer for the photo-oxidation of reactive side chains in the immediate vicinity. Jori and his colleagues examined two such sensitizers—the dinitrophenyl and the fluorescein thiocarbamyl groups. Their insertion caused no disturbance in the structure of the protein, as reflected in its optical properties. The dinitrophenyl group gave rise to its own Cotton effect in circular dichroism, indicating that it was rather rigidly set in its place in the protein. The fluorescein chromophore on the other hand showed no such effect, and from its low fluorescence polarization it could be inferred that there was little restraint on its rotation.

It might consequently be supposed that with its less restricted orientation it might function as a less discriminating photosensitizer. This expectation is borne out: the dinitrophenyl chromophore permits the destruction of only two residues, which were identified by separation of tryptic peptides as a histidine and a tryptophan. The fluorescein chromophore sensitizes the oxidation of both of these and also of a further tryptophan in the early stages of irradiation, and then increasingly indiscriminate destruction of residues in all parts of the chain. If the protein is denatured before irradiation, the side chains in the dinitrophenyl derivative are also extensively oxidized on irradiation.

From the papain structure, and indeed from what is known of its chemistry, the two residues destroyed in the native dinitrophenyl derivative are known to be in the active site, and no more than about 5 Å from the substituted cysteine. The protein so modified retains its native conformation, with unimpaired thermal stability. The second tryptophan initially modified in the fluorescein derivative is not in the active site, but is tucked into a tight-packed internal region close by. When this residue is oxidized, previously inaccessible groups become exposed, the optical properties change, and all the indications are that the tertiary structure has broken down. The conclusion is that the tryptophan in question is indispensable for maintaining the integrity of the conformation of the native enzyme.

A further refinement to the photo-oxidative approach has been evolved in the same laboratory (Jori *et al.*, *Biochim. Biophys. Acta*, **236**, 746; 1971). It is well known that paramagnetic ions are efficient quenchers of electronically excited states, and presumably for this reason are able to afford protection against photo-oxidative damage. The possibility then arises of making use of specific binding of such ions by proteins to achieve selective protection of some of the side chains which would otherwise be destroyed in a sensitized photo-oxidation process. Lysozyme is known to have a single strong binding site for zinc or cobalt. The site is known from protein magnetic resonance studies to consist of the carboxylate groups of glu–35 and asp–52. When the zinc complex is irradiated in the presence of proflavine as photosensitizer, tryptophan and methionine side chains are annihilated and the enzymatic activity vanishes. If on the other hand the paramagnetic cobalt ion is substituted for zinc the activity after irradiation does not fall below 85 per cent of native, and two indole rings are found to have been degraded. These are external side chains (trp–63 and 123), and do not perceptibly affect the conformation of the protein.

Experiments with ribonuclease gave similar results: the free enzyme or its zinc complex were extensively damaged but the cupric complex was modified only at two residues, met–79 and his–105, with substantial retention of activity. This result answers finally the question of whether met–79 is implicated in the enzyme mechanism. The protective effect of the paramagnetic ion is clearly a function of distance and orientation, and the possibility exists of exerting a finer control on the reaction by the choice of metal ions with different orientations of ligand orbitals.

Accurate Radio Source Positions from Cambridge

As the relationship between radio, optical and high energy emission from sources both inside our galaxy and from extragalactic sources is becoming increasingly important to an understanding of the processes operating in these objects, so it is of increasing importance that radio sources should be pinned down by accurate measurements of their positions. Without the painstaking work which this implies, no correlation can be made between radio sources and optical objects. Equally important is the establishment of an absolute reference scale, so that positions determined using different antennae can be adequately compared In next Monday's *Nature Physical Science* J. W. Smith reports the latest progress made in this field by the team operating the Cambridge One Mile radiotelescope.

By carrying out simultaneous observations at 2.7 and 5 GHz, corrections allowing for the curvature of the atmosphere, and seasonal variations in the electrical lengths of the delay cables in the equipment are included—these terms are as small as 0.01 arc s. The overall accuracy of the positions given by Smith for twenty-eight sources is not, of course, as accurate as 0.01 arc s. But the better than 0.05 are s accuracy quoted for right ascension, and better than 1 arc s for declination, is already pressing the optical astronomers, who will now need to improve their own measurements before a deeper insight into these sources can be achieved.

THE EARTH

Chondritic After All?

from our Geomagnetism Correspondent

THE chemical nature of the Earth's outer core has been a source of speculation ever since seismological evidence proved unequivocally that this part of the Earth is fluid. It is now completely accepted that the principal element in the core is iron although Earth scientists are rather less inclined to speculate upon to what extent such iron may resemble conventional molten iron under the conditions of temperature and pressure which obtain in the core. But this problem apart, the principal area of disagreement remains the content of the core's minor element. For various reasons the prime contenders here are nickel and silicon; but Murthy and Hall (*Phys. Earth Planet. Interiors*, **2**, 276; 1970) have suggested that the most important minor element may be sulphur.

It has long been known that where hydrated minerals (for example, hydrous silicates) are present, the low-temperature accretion of an Earth which is roughly chondritic requires the retention of sulphur as FeS under all conditions of temperature and pressure and thus requires the relative solar proportion of sulphur in the Earth as a whole. Various considerations thus led Murthy and Hall to argue that the first melt to form during the early history of the Earth was an FeS–Fe eutectic which would have effectively transferred chalcophilic elements from the lithosphere to the core, that a core with 15 per cent sulphur would have a density lower than that of any Fe–Ni alloy and would thus be more in line with many seismological estimates, that thermal models of the Earth which take account of the presence of FeS indicate earlier core formation than other models, and that to have had early core formation and differentiation of the Earth would have required neither high accretion temperatures nor a basic difference in chemistry between chondrites and the proto-Earth. There are, nevertheless, serious objections to a chondritic Earth in the first place, one of the most important of which is that the alkali metals, potassium, rubidium and caesium, are several times less abundant in the lithosphere than differentiation of a chondritic Earth would indicate.

Taking up the matter where Murthy and Hall left off, Lewis (*Earth Planet. Sci. Lett.*, **11**, 130; 1971) now argues that the presence of sulphur in the core removes many of the apparent discrepancies between the real Earth and the chondritic Earth. His basic thesis is that, contrary to popular supposition, the three "missing" elements, among others, have "appreciable chalcophilic tendencies" and that as a result their depletion in the lithosphere is balanced by their enrichment in a sulphur-bearing core. In other words, the relative lack of abundance of these elements in the lithosphere should not be extrapolated downwards and thus does not necessarily imply that the Earth cannot be chondritic as a whole.

Needless to say, there is little direct evidence for this, but Lewis can nevertheless point to certain factors which support his case. Thus although the oxide–sulphide equilibrium is not relevant, as such, to any process occurring in the interior of the Earth, equilibrium constants show clearly that the alkali and alkali metal sulphides are extremely stable with respect to the corresponding oxides—a fact which Lewis believes to be indicative if not definitive. Second, in ordinary chondrites the alkali metals are almost always present in the silicate minerals and not in oxides, sulphides or oxysalts. A consideration of the reactions of Mg_2SiO_4 and $CaSiO_3$ with FeS in relation to olivine at a temperature of 240° C above the FeS–Fe eutectic then indicates that small amounts of CaS and MgS are stable relative to FeS and thus are likely to enter an FeS–Fe melt even with silicates in the same state of oxidation as in the present mantle. Moreover, CaS and MgS have been found in many enstatite chondrites and achondritic meteorites; and some of such enstatite chondrites also contain sulphide phases containing Na, K and Ti. In Lewis's view there seems no reason to suppose that where K goes Rb and Cs should not also follow, especially because the equilibrium constants for these elements in the oxide–sulphide reaction are very similar.

The difficulty in proving Lewis's point lies largely in the lack of thermodynamic data on the behaviour of the relevant sulphides in FeS-rich melts; and matters are not helped by the almost complete absence of alkali metal sulphides in terrestrial rocks known to geologists. But in spite of the latter deficiency and the admitted difficulty of forming solid sulphides of Mg, Ca, K, Ti and Na, the impossibility of producing an FeS-rich melt with, say, a one per cent content of such sulphides is by no means clear. Indeed, the circumstantial evidence for such a mixture in the core is quite strong.

Lewis rightly points out that if the Earth's fluid core really is enriched in

---

Growth Regulation in Normal and Transformed Cells

IT is classic observation that mouse fibroblasts (3T3) cells stop growing when they reach confluence or when they are deprived of serum, whereas the same cells transformed by the oncogenic virus SV40 continue to divide. This system would seem ideal for gaining insight into the normal regulation of cell growth and the genesis of cancer, and consequently much information has accumulated about biochemical changes in the cells after transformation or during growth limitation. In next Wednesday's *Nature New Biology*, Hershko *et al.* extend these observations, and, grasping the whole nettle boldly by the hand, propose a unifying theory of growth regulation in animal cells and its disruption by tumour viruses.

They show that depriving untransformed, but not SV40 transformed, 3T3 cells of serum produces a marked inhibition of protein and RNA (particularly ribosomal RNA) synthesis, a reduction in the uptake of certain nucleic acid precursors and a stimulation of protein degradation. They argue that each of these diverse metabolic reactions is, independently, part of a coordinated programme, or "pleiotypic response", of normal cells to changes in growth conditions. The response may be "negative" or "positive" depending on whether growth is limited or stimulated. Considering the possible mechanism of the pleiotypic response, Hershko *et al.* show that all the changes elicited by serum deprivation are reversed by insulin, even when bound to 'Sepharose' and unable to enter the cell. This suggests that the pleiotypic response may be coordinated by an intracellular "mediator" generated at the cell membrane, much in the same way that cAMP brings about the diverse responses of tissues to activators of adenylate cyclase.

In support of their idea that several aspects of cell function are coordinated by a single, underlying mechanism, Hershko *et al.* draw a striking analogy between the negative pleiotypic response in animal cells and the "stringent" response in bacteria starved of essential amino-acids. The stringent response, controlled by a single *Rel* gene, was originally thought to affect only ribosomal and tRNA synthesis, but it now seems that other processes are involved, including the uptake and phosphorylation of certain nucleic acid precursors and glucose, the formation of polyribosomes and the degradation of protein, which are all elements of the pleiotypic response. For the present, however, the case for the defence must rest there, for the nucleotide ppGpp, implicated in the mechanism of the stringent response, does not seem to be present in normal, growth-limited, animal cells, and is therefore unlikely to be the postulated negative pleiotypic mediator.

K, Rb and Cs the consequences are at once numerous and far reaching. First, the relative depletion of the three elements in the lithosphere becomes immediately explicable; and the terrestrial abundances of the major elements become compatible with a chondritic source. Second, it is no longer necessary to invoke volatilization during high temperature accretion to account for the apparent disappearance of terrestrial potassium and sulphur. Third, it may no longer be necessarily true that the chondritic Earth model, which explains the observed terrestrial heat flow so well, is not valid simply because the crust and mantle do not contain enough K, U and Th. Fourth, as much as seven eighths of the ^{40}K in the Earth may be in the core, thereby forming a major heat source of about 10^{20} ergs s^{-1}. Even if the efficiency of conversion is only 10^{-4} there would be enough energy here to maintain the convection to produce the geomagnetic field.

The fifth point is that the rough equality of oceanic and continental heat flow, notwithstanding the greater concentration of radioactive heat-producing minerals in the continental crust, may be explained by convective upwelling of deep ^{40}K beneath the oceans. Sixth, the low abundance of ^{40}Ar in the atmosphere compared with the abundance to be expected from the decay of ^{40}K in a completely degassed chondritic Earth could be related to the impossibility of degassing radiogenic ^{40}Ar from the core. And, finally, the low abundance of ^{87}Sr in the crust may be the result of the removal to the core of much of the Rb early in the Earth's evolution.

But can so many consequences, covering, as they do, such a wide range of geophysical and geochemical problems, really stem from such a simple premise? It is possible, of course, that Lewis has underestimated the complexity of some of the problems his basic thesis purports to solve. Even so, his wide-ranging conclusions must surely force a re-evaluation of the problems which have turned most scientists away from the simple chondritic Earth.

PESTICIDES

Leaching from Soil

from a Correspondent

IT is well known that fish and other aquatic organisms may concentrate organochlorine pesticides from very low levels in the water in which they swim until the amounts in their bodies are either lethal or too high for the fish to be eaten by man, so that this form of environmental contamination has received considerable study. The 1970 report of the Agricultural Research Council's Research Committee on Toxic Chemicals showed that some organochlorine pesticides were likely to come from rainfall, but that factory effluents and accidents such as spills of sheep dip were more important. Measurable amounts of pesticides are washed off the surface of treated fields especially by flash floods, but "underground water, which has percolated through soil, has not been found to contain measurable quantities of organochlorines".

This conclusion is based on many observations, mostly in temperate countries. The British Ministry of Agriculture suffered some criticism for suggesting that the best way of disposing of surplus and unwanted DDT, shortly to be banned for use in gardens in Britain following the recommendations of the Advisory Committee on Pesticides and Other Toxic Chemicals (the Wilson Committee), was to rotovate it into the soil, though this is, in Britain, a method which is likely to localize the insecticide's effects, and is far safer than such methods as disposal down the drain, or bulk burial.

A disquieting report from Pakistan is contained in an article by Aslam I. Nasim, M. M. H. Baig and K. A. Lord, of the Toxicology and Pesticide Laboratory, Karachi (*Envir. Poll.*, **2**, 1; 1971). These authors have found that organochlorine insecticides are widely distributed in soils in East Pakistan and are extracted by water from the soil. Nasim *et al.* examined six soil samples from three different localities near Dacca by silica-loaded paper and gas chromatography and found that all were contaminated with organochlorine insecticides and contained 1 to 3 p.p.m. of DDT. Furthermore, three of the samples contained 0.1 to 0.5 p.p.m. gamma BHC and three others about 0.5 p.p.m. dieldrin. BHC has been used in the past in Pakistan for the control of rice pests and dieldrin is used in the treatment of bamboo, but there seems to be no easy explanation for the DDT contamination.

Because insecticides are leached from soil by water, the presence of 1 to 3 p.p.m. of DDT and other insecticides in the soils examined by Nasim *et al.* could pose a threat to the fish life inhabiting paddy fields as well as the more direct contamination of water sources. Nasim *et al.* consider it essential therefore that further monitoring continues—freshwater fish are important sources of protein for the population of East Pakistan, and any deleterious effects of the insecticides on the fish populations could be serious.

Hormone-responsive Tumours

A FAVOURITE pastime of steroid endocrinologists in recent months has been hunt-the-receptor-protein, and attention is now turning towards the determination of the physiological relevance of these proteins. One aspect of this concerns their role in steroid-controlled growth of certain tumours. In general, hormone responsive tumours show a progression from a responsive to an unresponsive state, and this is associated with a loss or diminution of specific steroid-binding capacity (King, Smith and Steggles, *Steroidologia*, **1**, 73; 1970).

In next Wednesday's *Nature New Biology*, Kirkpatrick, Milholland and Rosen report a decreased amount of corticosteroid receptor in unresponsive P1798 lymphosarcoma as compared with the corticosteroid-responsive line. This confirms the earlier work of Hollander and Chiu (*Biochem. Biophys. Res. Commun.*, **25**, 291; 1966), but Kirkpatrick and his colleagues have taken advantage of a factor not usually available in this type of work, that a parallel biochemical response (DNA synthesis and membrane permeability) can be measured as an indication of the relevance of the steroid protein interaction. They also show that, contrary to one of the current vogues of cancer research, changes in the cell membrane cannot explain their results.

An unanswered question is what or where is the primary lesion causing this loss? Recent reports indicate that steroid specificity is controlled at the nuclear level as well as by the presence of a cytoplasmic protein (Steggles, Spelsberg, Glasser and O'Malley, *Proc. US Nat. Acad. Sci.*, **68**, 1479; 1971) so it is possible that a change in binding may also occur at the nuclear level. Kirkpatrick *et al.* found that nuclear binding was low in the responsive cells, but do not mention the unresponsive ones.

A study such as this has several aspects that are relevant to tumour biology. First, it indicates that receptors are involved in steroid mediated inhibitory as well as activation processes. Second, it suggests that receptors may be translatable into clinical tests for the hormone responsiveness of human tumours; it is of considerable practical importance to decide which breast cancer patients will benefit from ablative endocrine surgery and oestrogen-binding experiments look hopeful in this respect. Third, the presence of a regulatory protein in a responsive cell and its loss or diminished binding potential in unresponsive cells (none of the experiments distinguishes between these two possibilities) have obvious analogies with enzyme induction in microorganisms.

AIRCRAFT DYNAMICS

Scheme of Notation

from a Correspondent

THE basic equations of aircraft dynamics are those of classical mechanics, with the elaboration that the forces and moments of aerodynamic origin are themselves influenced by the motions which occur. Aeronautical engineers are greatly addicted to dimensionless expressions because, when used with discernment, they often render generalities more apparent, increase the clarity of the work and yield succinct results. The equations of motion of an aircraft, together with appropriate systems of symbols, have therefore been the subject of much dimensionless invention for more than half a century.

The most familiar system in the United Kingdom has been that of Bryant and Gates (Aeronautical Research Council Reports and Memoranda (R&M) No. 1801 ; 1937) which separately defined dimensionless aerodynamic derivatives and inertial parameters. In the United States, a somewhat different system with broadly the same intentions was adopted. There have also been sundry variations on these themes and—to borrow a felicitous phrase from the latest number in the R&M series—the "clash of symbols" has been considerable. Moreover, the pre-war systems were devised largely in the context of small perturbations from a simple undisturbed condition, using only first-order derivatives. The behaviour of modern aeroplanes and the increasing importance of cross-coupling effects, the demands of aeronautical engineers concerned with missiles and the use of computers has rendered such systems inadequate.

R&M 3562 (H. R. Hopkin, *A Scheme of Notation and Nomenclature for Aircraft Dynamics and Associated Aerodynamics*, Parts 1 to 5, HMSO, 1970, £6.75) proposes a unified system of notation and nomenclature for the study of aircraft dynamics which seeks to avoid the limitations of the earlier systems, to be more self-consistent and to be capable of further expansion. It is the product of some years of discussion at the Royal Aircraft Establishment in cooperation with the National Physical Laboratory and is a most comprehensive and closely argued work. In the course of explaining the basis of the new system, it presents a useful survey of the whole of the fundamental concepts and definitions used in the field. The geometry associated with aircraft attitude, incidence and axis systems is presented in detail, although the quality of the diagrams is no more than adequate—rather better ones are provided in the Engineering Sciences Data Unit (ESDU) Data Sheets published by the Royal Aeronautical Society. The basis of the system is, inevitably, somewhat similar to that of R&M 1801 save that it has been recognized that it is preferable, in defining "normalized" or non-dimensional quantities, to treat the aerodynamic data and the equations of motion in slightly different ways. The dynamic-normalized system is intended for investigations of the dynamic behaviour of an aircraft of certain mass acted on by aerodynamic and other forces when travelling at a certain speed. The aero-normalized system is convenient for expressing functions of the aerodynamic forces acting on an object of certain dimensions when it is in a stream of air moving at a certain speed. An important change, compared with the previous British system, is that the unit of force is now the datum dynamic head multiplied by an area, as opposed to twice this quantity. The characteristic lengths are now the mean aerodynamic chord for longitudinal quantities and the span for lateral quantities. The new aero-normalized derivatives are therefore similar to the "old" derivatives (and are denoted by similar symbols) but differ, in some cases, by factors which may involve powers of two and ratios such as the mean aerodynamic chord of the tail moment arm. "Concise" derivatives are introduced, obtained by dividing a derivative by the appropriate inertial quantity and incorporating a sign change so that most derivatives become positive (for example, $m_q \doteqdot -M_q / I_y$). The system is then arranged so that the equations of motion have the same form whether they are dimensional or non-dimensional. The precise significance of a symbol can, if necessary, be made explicit by a suitable "dressing", but in most cases the context will be such that the dressings can be omitted, as has mostly been done in the ESDU Data Sheets. As Hopkin observes, however, "the undressing of symbols should be discreet". In the absence of dressings, the symbols will look very similar to those of the older system although their numerical values, signs and non-dimensionalizing factors will usually be different. Until the new system has gained general acceptance, authors should be careful to explain exactly how they are using it.

The Engineering Sciences Data Unit has already issued several Data Sheets on Aeronautical Dynamics using this system, and it seems that it will have the blessing of the International Organization for Standardization.

Understanding the Origin of Petroleum

FATTY acids have long been regarded as possible predecessors of n-paraffins in petroleum. Some years ago Jurg and Eisma (*Science*, **144**, 1451; 1966) heated behenic acid ($C_{21}H_{43}COOH$) with kaolinite and with kaolinite and water for varying lengths of time and produced small amounts of n-paraffins—principally $C_{21}H_{44}$—and unsaturated hydrocarbons and fatty acids. In next Monday's *Nature Physical Science* Shimoyama and Johns describe an experiment in which they heated the same fatty acid in the presence of Ca-montmorillonite.

The chief product was insoluble material deposited on the clay which they describe as kerogen-like. As in Jurg and Eisma's experiments the chief n-paraffin product was $C_{21}H_{44}$, formed by decarboxylation of the fatty acid. Smaller quantities of n-paraffins down to C_{16} were determined, and generally smaller amounts of n-paraffins in the C_{22} to C_{28} range. No fatty acids were detected in the products in contrast to Jurg and Eisma's findings and also to expectations based on their proposed reaction scheme. Failure to find new fatty acids may result from the use of Ca-montmorillonite instead of kaolinite or such acids, although formed, may have lost their identities by firm attachment to the kerogen-like product.

The production of $C_{21}H_{44}$ seems to have been halted by poisoning of the clay catalyst by the kerogen-like material. Shimoyama and Johns conclude that the C_{16} and C_{17} n-paraffins are produced by breakdown of the C_{21} paraffin, whereas C_{18}, C_{19} and C_{20} develop in the early stages directly from the fatty acid and later by disruption of $C_{21}H_{44}$. Composite plots of amounts of individual n-paraffins and behenic acid against time show the braided form suggested by Hobson (*Earth Sci. Rev.*, **2**, 257; 1966) for a breakdown sequence $A \rightarrow B \rightarrow C$ . . . . The dual origin of C_{18}, C_{19} and C_{20} yields hybrid curves.

With increasing age and maturity the larger n-paraffins in sedimentary rocks show a decrease in their carbon-preference indices, a measure of odd-carbon number dominance in the distribution of the molecules. Shimoyama and Johns's data for the C_{16} to C_{20} range show a comparable decrease with increase in time of heating and increase in temperature. But limited data on the C_{22} to C_{28} range show even-carbon number dominance, an unusual condition. Kvenvolden and Weiser (*Geochim. Cosmochim. Acta*, **31**, 1281; 1967) have noted a crude oil in which there is even-carbon number dominance in the C_{20} to C_{26} range and odd-carbon number dominance in the C_{27} to C_{33} range.

Tentative calculations based on the experimental data suggest the attainment of "mature" n-paraffin distributions under conditions approaching geological requirements of time and temperature.

SEAFLOOR SOILS

Engineering Properties

from a Correspondent

MOST of the surface of the Earth is covered by a film of marine soil, the properties of which determine the cost, hence the feasibility, of constructing on the seafloor all things from observatories to drilling installations. Do marine soils which have been recently deposited have a finite strength? A symposium to consider how best to cope with the fragility and other peculiarities of soils which have never dried was held from July 26 to 29 at the University of Washington, under the auspices of UNESCO and the National Science Foundation.

Charges on the sides and ends of settling particles cause marine soils to have an open, card-house fabric which is subject to collapse. Their sensitivity to stress is consequently extreme and disturbance may cause their strength to drop to a substantial degree. Dr D. G. True (US Navy Civil Engineering Laboratory, Port Hueneme, California) considered how best to measure the sensitivity of soils *in situ*, because it is impossible to transfer samples to the laboratory without changing them. A shear tester forces into the soil a cone or vane to about 3 m, then rotates it at one revolution per hour to measure "undisturbed" strength; this is re-observed after remoulding the sample by rotation at ten revolutions per minute.

An outline of current information about seafloor spreading by Dr R. S. Dietz (National Oceanic and Atmosperic Administration, Miami, Florida) made plain how profoundly tectonic processes affect everyday affairs; the areas adjacent to the continents are those which would be most useful for buildings, yet these are the areas of greatest instability. In some areas, for example the foreset slopes of major deltas and the flank of oceanic trenches, it may always be impossible to install permanent structures, because any disturbance could induce the downhill slide of sediments which have accumulated for millennia.

A theme present throughout the meeting was reminiscent of the exploration of space; is reward maximized by investing resources in a small amount of manned exploration, or in a comparatively large amount of purely instrumental exploration? Although submarine vessels have penetrated the deepest areas of the oceans, it is apparent that locomotion and manipulation in great depths remain awkward and expensive. Dr I. E. Mikhaltsev (Institute of Oceanology, USSR Academy of Sciences) made plain the advantage of operating on the seafloor rather than at the phase and storm interface occupied by surface vessels. This and other contributions brought into relief the fundamental importance of television as a means of controlling both manned and unmanned devices.

The strength of marine soils is difficult to assess because there is only a limited time in which to apply tests. Geophysical techniques, usually acoustic, encounter this difficulty in extreme form, because the stress used in tests lasts for only a fraction of a second. Dr D. Taylor Smith (University of North Wales) showed that such factors as acoustic attenuation bear a useful relationship to geotechnical properties including porosity, itself descriptive of long-term strength. Drs R. C. Bostrom and M. A. Sherif (University of Washington) pointed out that in sediment piles slopes diminish until stability is reached, so that seafloor topography is a description of long-term strength and can be used to quantify it. The stress is that of infinite period applied by gravity. The most urgent need, perhaps, is the development of a technique capable of observing long-term strength from a ship under way.

A special topics session discussed, among other things, the use of marine soils to cover waste material. It transpires (Dr B. Lehman, Lockheed Building and Construction Corporation) that it would cost $5 per ton to transport compressed waste from New York to the nearest tectonic trench, as against $10 to $20 to incinerate it. In an area penetrated by channels the bottom soil acts as a natural seismic recorder (Dr R. E. Sylwester and others, University of Washington) so that it is possible to map active fault traces invisible on land.

MICROEARTHQUAKES

Geothermal Fault

from our Geomagnetism Correspondent

THE discovery that fluid injection may produce seismic activity along previously inactive faults could prove to be the most socially significant geophysical advance of the century should it prove possible to apply it to the gradual release of strain in active, and potentially dangerous, faults. At present, however, the successful modification and control of earthquakes are far from reality, and a greater understanding of the fundamental processes involved will be required before such hopes can progress much beyond the theoretical stage. Work proceeds in the meantime on several fronts which range from controlled experiments away from human habitation to the observation of natural events and seismic situations created inadvertently by man himself.

Perhaps the most obvious situation in which nature provides its own fluids is the geothermal field; and it seems likely that such fluids will have some effect on faults which cross the field. It is possible, of course, that faults in geothermal regions might be active even in the absence of fluids; but what is quite certain is that microearthquakes are observed in many major geothermal areas such as those in Japan, California and Iceland. And as Ward and Jacob (*Science*, **173**, 328; 1971) now show from a study of the Achuachapan Geothermal Field at El Salvador (Central America), these microearthquakes may be used to map active faults. Indeed, where large earthquakes are either rare or completely absent microearthquakes may provide the only means of fault mapping.

As it happens, between 1961 and 1970 the US Coast and Geodetic Survey reported thirty-two events with magnitudes greater than 3.5 and having epicentres within 60 km of Achuachapan; but depths of focus ranged from 16 to 276 km, so that it seems unlikely that these events were related directly to near-surface geothermal activity. By contrast, between December 7, 1969, and August 10, 1970, Ward and Jacob detected about 500 microearthquakes with magnitudes ranging down to 0. From the distribution of S-wave minus P-wave arrival times it is clear that two groups of events were present. Some 350 of the events had S–P times of more than 8 and were probably associated with a seismic zone which dips north-eastwards under El Salvador. But almost all of the remaining 150 or so had S–P times within the range 0–2; and it is these which were apparently related to surficial geothermal activity. These local events frequently occurred in swarms of ten to twenty events separated in time by up to several weeks. Unfortunately, because of operational problems the foci of only seventeen of the local microearthquakes could be located with any degree of precision, but these were sufficient to define a fault plane intersecting most of the foci and passing through a point where fault breccia was observed in a drill hole. This plane was roughly parallel to normal faults previously mapped to the north-west.

This is not the first time that microearthquakes have been used to map an active fault; but it is a significant case because of the association with geothermal fluids. Thus Ward and Jacob interpret the detected fault as the one which allows the hot geothermal water to reach the surface. If this is a valid interpretation the technique should prove to be of economic importance in that it would be of obvious advantage to site geothermal production wells close to the chief source of upwelling hot water.

Statistical Mechanics and Quantum Mechanics

G. E. UHLENBECK

Rockefeller University, New York

Part of the acceptance speech on the occasion of the award of the Lorentz Medal by the Royal Netherlands Academy of Sciences on June 27, 1970.

ARE the problems of statistical mechanics truly fundamental? I have often changed my opinion and now I would like to elaborate on it. When I was a young student, kinetic theory of matter seemed to me an example of a theory which truly explains something. With much care and effort I worked my way through the *Lectures on Gas Theory* by Boltzmann and the *Elementary Principles of Statistical Mechanics* by Gibbs. Much escaped me and became clear only after I read the famous encyclopaedia article by the Ehrenfests. It was a revelation, not only because of its great clarity but also because it contained a careful summing up of the series of more-than-twelve *lacunae* in the work of the masters. These were like frontier posts and a young student could thereby learn where the real problems lay. How difficult it is to find this out nowadays. The present pollution of the scientific literature makes the finding of clear water, the fundamental concepts, an extremely time consuming occupation. This is true not only for the new student but for anyone who tries to learn something outside his own speciality, as I well know by experience.

Though I passed my examinations successfully, I knew very little of quantum theory and even less of the theory of spectra. I learned that, with Goudsmit's help, when I returned from Rome in 1925 and became Ehrenfest's assistant. I shall not elaborate on the collaboration with Goudsmit, which I shall never forget and which led to the discovery of electron spin. Both Goudsmit and I have often related our memories of this unforgettable period and I mention it only because at that time my conception of statistical mechanics changed completely. I considered it to be clearly on a secondary level. Quantum mechanics on the other hand provided a foundation from which everything should follow, including the behaviour of gases, liquids and solids. This seemed to be confirmed by the success of the electron theory of metals. Pauli and Sommerfeld (both recipients of the Lorentz Medal) showed how all difficulties disappeared as soon as one applied the true quantum statistics. A few riddles remained, such as superconductivity, but in our optimism we felt sure that all would be straightened out eventually. My dissertation in 1927 about statistical methods in quantum theory was therefore a kind of optimistic synthesis of the encyclopaedia article of the Ehrenfests and the new quantum mechanical ideas. The number of unproved assumptions was reduced to three.

Later in Ann Arbor, the beautiful experiments of N. H. Williams on thermal noise and shot noise aroused my interest in the theory of Brownian motion, one of the nicest applications of statistical mechanics. I thought it very interesting but of course it was not fundamental. I remember very well that when I told Pauli about it he called it "desperation physics". I didn't like this but I really agreed with him. For a physicist of the quantum mechanics generation to which I also belonged, the fundamental problems of the 1930s were the theory of the positron, quantum electrodynamics and the developing theories of nuclear structure and beta radioactivity; these were the things on which to work.

Let me say at this juncture that the image of progress in science as a kind of conquest of an unknown domain with a definite "frontier" and successive "breakthroughs" seems to me more and more to be only a romantic illusion. This picture was clearly inspired by the great breakthrough of quantum mechanics and it has influenced my judgment for a long time. I might even say that I was afflicted by it.

My opinion about the fundamental character of statistical mechanics began to change in 1937 to 1938 when I, together with Boris Kahn, became involved in the so called condensation theory. The question why a gas condenses below a sharply determined critical temperature at a sharply determined density has never been called to attention since Van der Waals and the proper understanding of it seemed difficult to us. During the lively discussion about this question at the Van der Waals Congress in 1938 it was even doubted whether the basic assumptions of statistical mechanics contained the answer even in principle. This doubt was not justified, but it made a deep impression on me. As long as such common phenomena as the equilibrium between liquid and vapour and the existence of a critical temperature were not truly understood, the field was not yet conquered, not everything had been explained in principle and thus there existed fundamental aspects of statistical mechanics which I had not appreciated.

(When I showed Pauli the article by Kahn and myself on condensation theory he looked at it and said, "Yes, one should read this". He did so and ridiculed somewhat the quasi-mathematical rigour of our work but I believe that he appreciated the fundamental character of the problem.)

After the war, I continued to follow the new developments in quantum electrodynamics and the theory of beta radioactivity, and from time to time I contributed a little. But my interest moved more and more towards the fundamental questions of statistical mechanics. In the 1950s I began to write a book on statistical mechanics with my pupil and friend, the late T. H. Berlin. I hoped that it would become a modernized and expanded version of the encyclopaedia article which had made such an impression on me. I hoped that we could determine the foundations of the theory in the same critical way as the Ehrenfests, and that we could make clear the nature of the still unsolved basic problems. In short, I hoped that we could discover the "structure" of statistical mechanics.

We worked hard on it but did not get very far and the sudden death of Ted Berlin in 1962 makes it doubtful that our plan will ever be realized. I have learned a lot from it, however, and I have the feeling that I more or less understand the structure of classical statistical mechanics at least. I believe that one always has to keep in mind that the task of statistical mechanics is to study the relationship between the macroscopic description of

Che istry Librar

physical phenomena and the microscopic molecular description. These two pictures are in a certain sense independent; moreover, they are, so to speak, on a different level and are therefore, even qualitatively, totally different. If one sticks to this idea, one can see that Boltzmann, Gibbs, Einstein, Ehrenfest and Smoluchowski have formulated the true basis on which one has to build further. One sees also that there are still many unsolved problems, such as condensation and other so called phase transitions, on which much work is being done. All these problems are very difficult but they are, as a mathematician would say, *bien posés* and therefore one can work on them.

In my opinion the situation is somewhat different for quantum theory. The relationship between the classical and quantum mechanical descriptions of molecular phenomena is rather clear, but this is not so for quantum mechanics and the macroscopic theory. I am aware that this opinion is not shared by most of my colleagues. I believe that the most widespread opinion is that quantum mechanics can be "grafted" onto the classical statistical mechanics of Boltzmann and Gibbs and that therefore quantum mechanics does not require anything essentially new. I had thought so earlier too, but I have slowly retreated from that conviction. The recent discoveries of so called macroscopic quantization and interference phenomena in liquid helium and superconductors have had a great influence on my ideas. They seem to me to show that the existing theories of superconductivity and superfluidity do not provide a complete explanation and that the true macroscopic description of the superfluids has not yet been found. It would be no surprise to me that this is so because the foundations of quantum statistical mechanics have not yet been sufficiently clarified. One only needs to think of the persistent currents to feel doubt about the general validity of the ergodic theorems in quantum theory. Questions like these make low temperature physics so fascinating for me; they have had a rejuvenating effect on me and I am convinced that there is still much to be done on this "frontier" of physics and that profound surprises are possible.

Because I use the word "frontier" let me finally return to the romantic image of advances in science which I sketched earlier. I do not believe in it any longer. There are many frontiers and it comes down to the fact that in science one can only sometimes talk of progress. Whenever there is an advance there is a frontier, not the other way around. As to the direction of the advance, every investigator follows his own nose and does what he can. In my opinion this applies equally to space travel and to high energy physics and radio astronomy. These pursuits exist because they are possible and as long as the expense does not become too exorbitant one must, of course, continue them. But I think that one must oppose all fashion and prestige arguments. There is no natural hierarchy of problems and moreover, as Poincaré remarked long ago, a problem is never completely but always only more or less solved.

It seems better to me to view progress in science as the expansion of different circles of investigation, each autonomous and often apparently entirely independent of the others. The deep problems are to determine how these areas hang together, and how one can arrive at a larger unity. Biology and physical–chemical research, for example, form two such large circles. Their interrelationship seems to me to represent one of the deepest questions man can ask, a real *mysterium tremendum*. On a much smaller scale macroscopic and molecular physics form two such circles and statistical mechanics attempts to fathom their relationship.

Research Environments and Productivity

S. P. GUPTA & K. D. SHARMA

Research Survey and Planning Organization, CSIR, New Delhi-1

The productivity of Indian scientists has been investigated with a view to identifying the environmental factors that influence it. These findings may help policy makers and science managers to create the necessary environmental conditions.

OUR study of productivity has been based on data collected for a report called *Opinion Survey of Scientists and Technologists*[1]. About 9,000 questionnaires were sent to the heads of all the national laboratories, other government and autonomous research institutions, private/industrial research organizations and departments of science, engineering and medicine in universities. The heads of institutions were requested to distribute the questionnaire among an approximately equal number of researchers not below the rank of

Table 1 Characteristics of the Sample

Characteristics: age group	Percentage	Characteristics: organizational settings	Percentage
21–25+	1.9	National laboratories	18.1
26–30+	17.9	Govt. res. institutes	22.2
31–35+	26.7	Private/industrial res. institutes	6.2
36–40+	26.3	Univs./teaching institutes	53.5
41–45+	12.1		——
46–50+	8.2		100.0
51–55+	4.5	Years since PhD	
56–60+	1.0	0–5+	45.6
Above 60	1.4	6–10+	30.6
	——	11–15+	13.5
Total	100.0	16–20+	5.8
Median age	(36.6)	Above 20	4.5
			——
		Total	100.0

Table 2 Average Publication per Year with Standard Deviation for PhD Scientists according to Age Groups

Age groups	No. of respondents	Mean* publications per year	Standard deviations
21–25+	10	1.3	1.6
26–30+	92	1.8	2.5
31–35+	137	2.4	3.5
36–40+	135	2.6	3.4
41–45+	62	3.2	4.5
46–50+	42	2.7	3.0
51–55+	23	4.6	3.9
56–60+	5	3.4	2.1
Above 60	7	2.8	2.2
Total	513	2.6	3.4

* Statistically significant at 0.05 level.

laboratory assistants. No information was available as to how the distribution in each institution was effected, but the sample seems fairly representative of various ranks and disciplines.

An important factor influencing the size and composition of the sample was the willingness or unwillingness of heads of institutions to cooperate. In the absence of a roster of Indian scientists and of the ability to collect the data personally, the only course was to approach the respondent through heads of institutions to ensure a maximum, rapid return. But in many cases cooperation could not be obtained and, as a result, some institutions returned no questionnaires. In all, about 2,300 replies were received in five months—roughly a 25% return. After several rejections due to incomplete information, the total sample analysed stands at 2,143.

We have considered PhD scientists only because scientific productivity is assessed in relation to "professional age"[2] (the number of years since obtaining the PhD). Table 1 summarizes the important characteristics of the sample considered in this article.

We have measured scientific productivity by objective criteria, such as the number of papers, books and patents published. In constructing the index of productivity, a book was considered equivalent to four scientific papers in terms of contribution and efforts[2].

Individual Variables and Productivity

In the first stage of analysing our findings, we tried to discuss some major individual variables, such as age and place of work, with relation to productivity. Table 2 shows the mean number of publications per year and standard deviations in different age groups and also for the combined groups. The age of the respondent varied from 21 to 65, with a median age of 36.6 years, and the mean output of the combined groups during the period under study was 2.6 publications per year. The consistent upward trend in publications with age is indicated up to the age of 55, after which it decreases. The average number of publications per year is highest in the age group 51–55. When group means within each category are compared, the findings are statistically significant at the 0.05 level.

Table 3 Average Number of Publications per Year with Standard Deviation according to Four Organizational Settings

Organizational setting	No. of respondents	Mean* publications	Standard deviation
National laboratories	93	2.2	2.4
Government research institutes	114	2.9	3.6
Private/industrial research institutes	32	2.6	4.3
University/teaching institutes	275	2.6	3.4
Total	514	2.6	3.3

* Not statistically significant.

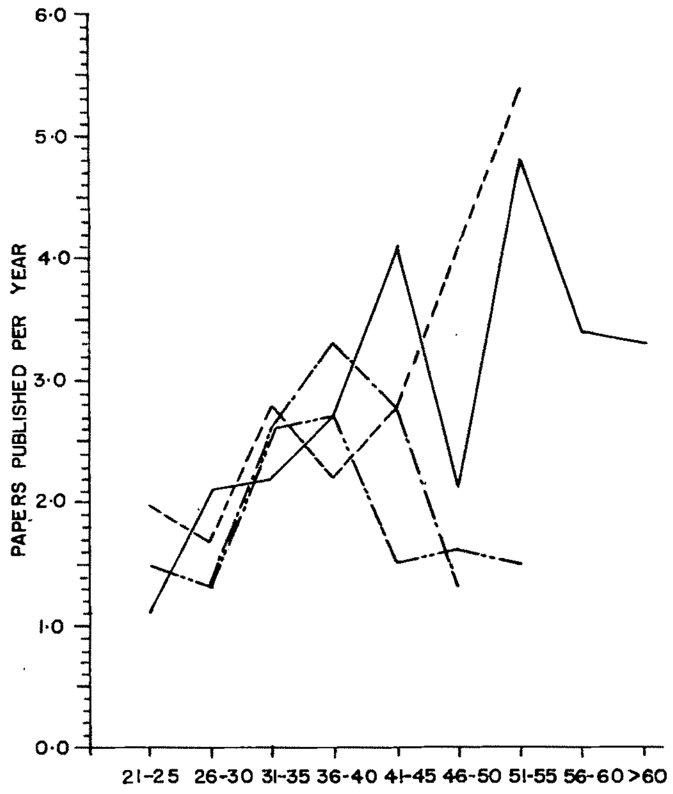


Fig. 1 Productivity of scientists in different age groups and types of organization. —··—, National laboratories; ----, government research institutions; — · — · —, private industrial research institutions; ———, universities and teaching institutions.

Agewise Productivity

Table 3 shows that organizational setting has no influence on the mean publication rate. The insignificant difference between the mean number of publications in different organizations could be due to large variance within each category. Hagstrom[3] finds considerable differences between the contributions of industrial and academic scientists to the growth of science. This is because the managers of industry are anxious to see the findings of their research scientists fully covered by patents before publication in scientific journals. The results of our study do not support Hagstrom's hypothesis. In India, it is quite likely that industrial management puts no constraint on the publication of papers in scientific journals.

Fig. 1 shows the productivity of scientists for different age groups in various organizations. In national laboratories the productivity rate seems to be highest when scientists are in their late 30s and the curve shows a sharp decline thereafter. A similar trend is evident for the scientists in private and industrial research institutes. The findings for these two types of organization are consistent with those of Lehmann[4] and Meltzer[5], who found the greatest productivity in the late 30s and early 40s, followed by a decline.

There is a trend for scientists in government research institutions to increase in productivity between 40 and 55. In the university and other teaching institutes, the productivity increases constantly until the early 40s and then declines between 45 and 50. After that the curve shows an upward trend in the early 50s, before relapsing again. In spite of overall differences in slopes, there are some remarkable similarities among these curves. The ages of best achievement

Table 4 Average Number of Papers in Relation to Recognition in Various Age Groups

Age group	Recognition High	Recognition Low
21–25+	2.0	1.5
26–30+	2.4	1.9
31–35+	2.9	2.2
36–40+	2.8	2.2
41–45+	2.3	2.7
46–50+	3.5	2.3
51–55+	3.1	5.0
56–60+	NA	NA
Above 60	NA	NA

in national laboratories, private and industrial research institutions, and to some extent universities and other teaching institutions, are quite similar. The late 30s and early 40s are the most productive periods in the lives of scientists except for those working in government research institutions.

Recognition, Age and Productivity

Recognition is an indicator of scientists' merit and social worth. In science, two most general forms[6] of recognition are: the immediate supervisor's evaluation of current research work and the credits for research publications. For our study recognition was measured largely through self-evaluation by the respondents themselves. If the respondent felt that he was highly appreciated by his supervisor and given preference in authorship, it was taken to indicate high recognition, otherwise he was categorized as having low recognition.

When recognition is examined in relation to productivity, keeping age groups constant, the results are quite interesting (Table 4). Productivity is low for scientists with low recognition. Although recognition is important to all scientists, younger scientists are more concerned about it, for they feel that it is essential if they are to establish themselves. Therefore, one of the environmental condition conducive to higher productivity in younger scientists is recognition. Another important outcome of Table 4 is that after the age of 50 organizational recognition is not important in the productivity of scientists, perhaps because at this age they are well established.

Freedom and Productivity

We have inferred the extent of freedom in research from the extent of autonomy in the selection of projects. Like the index for recognition, this has been reduced to two classes—high and low degrees of freedom.

Table 5 Publication per Year as Related to Freedom in Various Organizations

Organizational setting	Freedom High	Freedom Low	P*
National laboratories	2.4	2.0	n.s.
Government research institutes	3.4	2.2	0.05
Private/industrial research institutes	3.2	1.6	n.s.
University/teaching institutes	2.8	2.1	n.s.

* Significant level.

Our chief concern was to find out how scientists perform in these two categories of freedom. Table 5 shows the publications per year in various organizations where freedom is variable. It shows that the average number of publications per year is greater when there is a high degree of freedom than when there is a low degree of freedom in all four organizational settings. The differences within the organization were not statistically significant, however, except in government research institutes (other than national laboratories). It seems paradoxical that professional freedom has no bearing on productivity. In our study the emphasis was on freedom to select research projects, whereas a scientist is probably more concerned with the freedom to attack the problem and comparatively less bothered who selects the project for him. It is quite likely that the scientist wants least interference in his day to day work.

Prospects for Future Productivity

The results of our study present an interesting picture of Indian science. For the total sample productivity increases until the age of 55, and then declines. This contrasts with the finding of Pelz and others[7], and so this aspect was studied in detail for each organization (Fig. 1). It can be seen that productivity increases with age for: (i) government research laboratories, and (ii) teaching institutes and universities. In the case of national laboratories and private industrial research institutes the trend follows the international pattern, but for government laboratories and universities it shows a secular increasing trend, for which there is no obvious reason. Perhaps in government research laboratories and universities and teaching institutes authorship is based on seniority in the administrative hierarchy. But there may be other reasons, and it would be interesting to identify the factor responsible for the continuing increase of productivity with age in these institutes. It might then be possible to replicate these conditions in other institutes to augment the productivity of Indian scientists.

Scientists in national laboratories are less productive than their counterparts in organizations such as government research institutes; private and industrial research institutes, universities and so on. It is also evident that scientists in government research institutes have the highest productivity. It is interesting that this correlates with increasing productivity with age. This again tends to support the hypothesis that in government organizations, it is the hierarchy that decides the authorship rather than the actual participation in the research project.

Recognition and freedom have been suggested as motivating environmental factors which influence the productivity of scientists. From the operative point of view, the influence of these factors varies with age. We have found that people in the higher age group are neutral to recognition while those in the younger age group seem to be very susceptible to it. The lack of influence of freedom to choose projects on productivity needs to be studied further in view of the fact that the conflict between administrators and scientists revolves round control and freedom. In another study (unpublished) we found that freedom was a neutral factor with regard to the commitment of scientists to organizational goals. This could be explained by a lack of precision in the definition of the term "freedom" in the questionnaire, or a difference of opinion among scientists about the meaning of the term. In India scientists seem to be indifferent to this type of freedom. They probably interpret freedom as the opportunity to attack a problem without hindrance.

We have attempted to isolate a few of the environmental variables which influence the productivity of scientists. If these factors are properly manipulated, it is possible to increase productivity, and so it is essential that policy makers should consider these aspects more seriously.

Unique Bedrock and Soils associated with the Teesdale Flora

G. A. L. JOHNSON & D. ROBINSON

Department of Geology, University Science Laboratories, Durham

M. HORNUNG

Nature Conservancy Research Station, Bangor

This article describes the geological factors which have contributed to the formation of the unique bedrock geology and soils of the metamorphosed limestones on Widdybank and Cronkley fells in Upper Teesdale. The survival of the relict arctic–alpine flora is probably directly related to the distinctive geology of the area.

THE distinctive relict arctic–alpine flora of Upper Teesdale, Co. Durham and North Yorkshire, has been famous in biological circles for more than a century. In a subarctic environment, not quite warm enough for the growth of trees, there occur many species of flowering plants, pteridophytes, bryophytes and lichens which are rare in the British Isles and a few species which are not known in Britain outside Teesdale[1–4]. The flora includes a number of plants belonging to widely differing phytogeographical groups and has been interpreted as a relict flora from the vegetation that colonized Teesdale shortly after the end of the Quaternary glacial period. The flora has survived through the post-glacial forest and blanket bog intervals in Teesdale partly on rendzina soils associated with rotted crystalline marble on Widdybank and Cronkley fells[1,3].

Stratigraphy and Structure

The structure of Upper Teesdale is dominated by a north–south trending, east facing faulted monocline called the Burtreeford Disturbance[5] that has an eastward downthrow of some 200 m (Fig. 1). On the west, upfaulted side of this structure, Skiddaw Slates and tuffs of Ordovician age are exposed in the sides of the Tees at Pencil Mill, forming a small and poorly exposed inlier in the valley floor[5]. An angular unconformity separates the folded Ordovician from the overlying almost horizontal Carboniferous marine strata. The Carboniferous sequence[5] commences with a Basement Group composed of conglomerate and sandstone beneath dark limestones and shales about 25 m thick. The succeeding Lower Limestone Group is dominated by the Melmerby Scar Limestone, a light coloured limestone 38 m thick, which is separated into thick beds with thin shale and sandstone partings. Above the Melmerby Scar the upper beds of the Lower Limestone Group and the overlying Middle Limestone Group are composed of a rhythmic sequence of predominantly dark coloured limestone bands with intervening shales and sandstones. Significantly the Teesdale relict flora is found particularly in association with outcrops of metamorphosed light coloured Melmerby Scar and Robinson limestones and not with the overlying unaltered darker pigmented limestones.

It is probable that a full sequence of Carboniferous sediments was laid down in Teesdale followed possibly by Permian and Mesozoic deposits, but no evidence of these beds remains because of extensive Tertiary erosion which has removed any younger rocks.

Towards the end of the Carboniferous period uplift, compression and doming of the region took place and the Great Whin Sill quartz–dolerite intrusion was emplaced. The heat of intrusion baked and altered the sediments above and below the sill, producing new minerals and textures in the altered rocks contributing significantly to their present nature.

In Teesdale the Burtreeford Disturbance was active before the emplacement of the Great Whin Sill. The sill cuts across the faulted monocline from a position near the Tyne Bottom Limestone, within the Middle Limestone Group, on the east to a horizon near to the base of the Melmerby Scar Limestone on the west (Fig. 1). On the west of the disturbance the sill, 73 m thick, nears its maximum thickness and is at its lowest stratigraphical horizon. In all directions it tends to rise in the Carboniferous succession and decrease in thickness away from this centre[6,7].

After the emplacement of the Whin Sill, hydrothermal mineralization commenced in the Pennine region. This process is believed to have extended over at least 100 m.y. (ref. 8) producing economic galenabarytes veins in Upper Teesdale. The veins have been extensively worked in the region, notably at Cow Green Mine, and trial workings, chiefly for lead ore, are present on Widdybank and Cronkley fells.

A further important factor in the history of Upper Teesdale is the long period of erosion, perhaps 50 m.y. from the early Tertiary to the present day, that has removed the younger rocks and exposed the Whin Sill within the Melmerby Scar Limestone on the floor of the valley. The almost flat top of the sill forms a wide bench on Widdybank and Cronkley fells and the overlying crystalline marbles outcrop extensively though often masked by superficial glacial drift. The morainic drift and peat deposits, formed during Quaternary glacial and post-glacial times, have also played a significant part in the formation of the biologically important soils.

Whin Sill and Metamorphism

On Widdybank and Cronkley fells metamorphism of the Melmerby Scar Limestone and associated sediments occurs above and below the Great Whin Sill. The limestone is recrystallized for more than 25 m from the contact and the metamorphic effect can be detected to almost 40 m above and below the sill on the basis of spotting in shales. Elsewhere in northern England, where the sill is thinner, the effect of metamorphism is restricted to beds close to the contact.

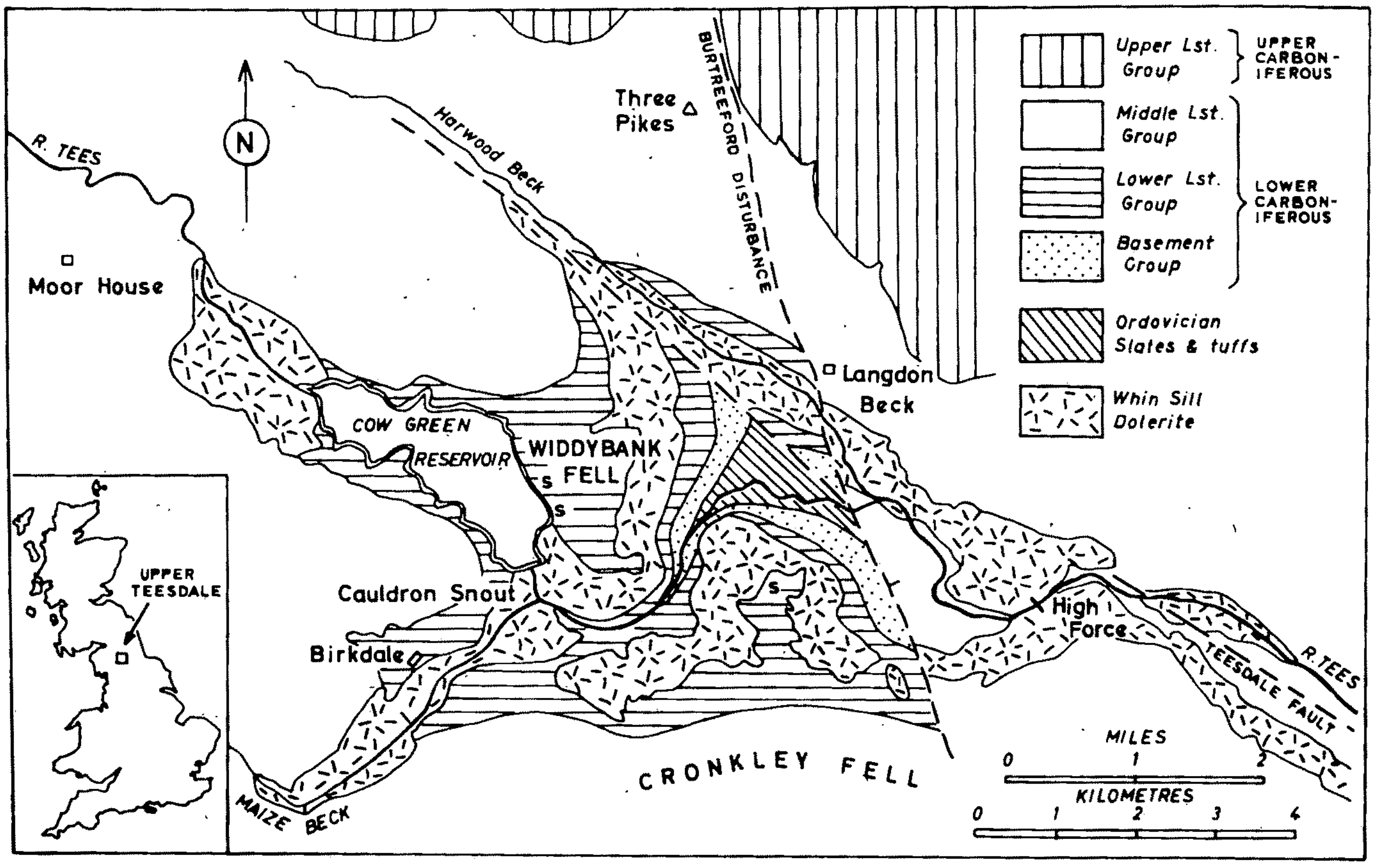

Fig. 1 Geological sketch map of part of Upper Teesdale showing the outcrop of the Great Whin Sill and the principal groups of sedimentary rocks. *S*, Well developed rotten marble and calcite sand rendzinas.

The alteration of pure limestones is limited to simple recrystallization. Impure limestones close to the contact form calc–silicate rocks in which a wide variety of minerals are present. Shales adjacent to the Whin Sill are converted into hard porcellaneous rocks (whetstones) in which the bedding is lost. Further from the contact spotted shales are commonly developed. Pure sandstones are converted into white quartzite at the contact and impure sandstones develop alteration patterns depending on the amounts of argillaceous or calcareous material present. The mineralogy of contact rocks associated with the Whin Sill in Teesdale has been described recently by Robinson[9].

The pure Melmerby Scar Limestone of Widdybank and Cronkley fells is recrystallized by the Whin Sill to a saccharoidal marble for about 25 m from the upper contact; a small thickness of marble is also present below the sill. The marble consists of dodecahedral to rounded grains of calcite varying in average grain size from 0.5 mm at the contact to 0.05 mm at a distance of 18 m above. The dark pigmented limestones, found principally in the Middle Limestone Group, are not recrystallized because the carbonaceous organic matter causes the suppression of marmarization[10]. Thus where dark limestones are found near the Whin contacts very little or no crystalline marble is found.

The formation of marble in Upper Teesdale is clearly the result of three factors combining to form a bedrock formation unique in northern England. First, the Whin Sill is near maximum thickness and lowest stratigraphical horizon. Second, the sill is injected into the thickest limestone in the Carboniferous succession of the region, the Melmerby Scar Limestone. Finally, the low carbon content of this pure, light coloured limestone allowed metamorphic recrystallization to take place readily, with the development of thick marble formations.

Weathering of Crystalline Marble

The marble outcrop is partly masked by patches and tongues of glacial drift on Widdybank and Cronkley fells. This is a pattern of exposure that has not changed greatly from the early post-glacial period when continuous vegetation cover stabilized the unconsolidated drift slopes. Since then peat has developed over impervious deposits, particularly the clay drifts, and thin soils have formed over exposed bedrock.

Weathering of bedrock crystalline marble takes place both at the surface, by processes of subaerial erosion, and below the surface at the bedrock drift or mineral soil interface. At the surface a hardened crust tends to form on the marble and erosion may be relatively slow except near to the Whin contact where the coarsely crystalline rock is often readily attacked by subaerial weathering processes. At the subsurface junction of bedrock marble and overlying drift or soil, percolating ground water causes solution weathering leading to loss of cohesion between calcite grains in the marble. Sections through the drift-marble interface show rotten saccharoidal marble or calcite sand deposits 0.25 to 3.0 m thick. The thickness of the layer and the rate of weathering of the marble are dependent on the amount of ground-water movement. Subsurface erosion sufficient to produce hollows in the land surface has taken place as the rotted marble is removed in solution.

From these observations it follows that the unconsolidated calcite sand, known to a succession of biologists as "sugar limestone", is chiefly a subsurface weathering product of saccharoidal marble formed beneath a cover of drift and soil. Its presence at the surface today is caused by contemporary erosion of the soil and drift cover. Calcite sand is a most unstable surface deposit which tends to erode by rain and wind action at any place where the protective drift, soil or vegetation cover is removed. A cycle consisting of subsurface weathering below thin soil followed by erosion of unstable calcite sand may have taken place on crystalline marble outcrops on Widdybank and Cronkley fells during much of the post-glacial time. This would provide a succession of open habitats suitable for the survival of the arctic–alpine flora. Because of its instability and secondary origin it is unlikely that calcite sand deposits were present on these outcrops during the period of initial plant colonization in late-glacial times.

Soil Development

The presence or absence and thickness of drift cover have been important factors in determining the soils developed over crystalline marble on Widdybank and Cronkley fells. Under continuous drift, more than 60 cm thick, the limestone acts chiefly as a platform on which soil formation takes place in the upper layers of the drift cover. The limestone exerts some influence on soil formation by maintaining free drainage in the subsoil and lower drift, even though the latter is often of heavy texture. Peaty gleyed podzols or deep peat are the resultant soils. Where the superficial drift cover is thinner (30 to 60 cm) the limestone maintains free drainage, but also exerts an influence on the chemistry of the soil so that brown earths or brown calcareous soils result. Where there is only a thin layer of superficial material, less than 30 cm thick, the bedrock marble dominates soil formation and rendzinas are the resulting soils.

The rendzinas form part of a complex in which three subtypes, for the purpose of this paper called α, β and γ, occur in association with small areas of brown earth soils. The brown earths are found over patches of deeper superficial material. The rendzinas are characterized by alkaline reaction and excessive drainage such that even short dry periods cause a water deficit[11]. Rendzina α is the simplest and forms *in situ* from rotten crystalline marble. The profile is divisible into a dark grey, humic but sandy surface horizon (A or A_h) which has a dense mat of fibrous roots, and an underlying C horizon of white or cream coloured calcite sand. Formation of α rendzinas requires the prior removal of any superficial drift with exposure of the underlying marble to subaerial erosion and soil forming processes.

Rendzina β is the most widespread in the rendzina complexes. It develops over crystalline marble bedrock in regions where drift parent materials play an important part in profile formation. A typical profile is composed of a thin horizon (up to 10 cm) of dark brown or reddish brown clay or silt loam over calcite sand resting on relatively unaltered marble. The colour and texture of the surface layer vary considerably. Colour variation reflects a number of factors but bright coloured reddish variants have a high content of total iron present as hydroxides. The bright red soils overlie marble cut by fine siderite veins which oxidize to hydroxides of iron including goethite. The soils inherit their coluration and high iron content from the vein material, fragments of which are normally present in the soils. Textural variation depends on changes in the proportions of sand and clay with the silt fraction remaining fairly constant. The soils also contain small stones which have been derived from the surrounding drift. The loam is clearly of mixed origin containing contributions from the drift and the underlying marble; mixing probably took place during pedogenesis.

Rendzina subtype γ is a closely related group of soils which have aeolian erosion and depositional characteristics as a uniting feature. They form a small part of the total rendzina complexes and show much variation in detailed profile morphology. These rendzinas are particularly well developed in the Thistle Green area, Cronkley fell, where they are associated with and abut against bare areas of calcite sand. Profiles of rendzina γ almost always contain a number of buried surface horizons and clear evidence of surface accretion. Observation on a windy day immediately demonstrates that aeolian movement and deposition are active and sufficient to produce profile accretion. These soils were formed under conditions of periodic erosion, aeolian transport and deposition of calcite sand. Readily identifiable old surface horizons within the rendzina γ profiles support an origin by periodic deposition rather than continuous accretion. Periodic erosion of limestone sand would produce areas available for plant colonization and would aid the survival of the Teesdale flora.

The typical rendzina profiles differ markedly from soils developed over unaltered Carboniferous limestone though the rendzina β subtype grades imperceptively into normal limestone soils away from the Whin Sill contact as the bedrock changes from coarse to fine grained marble. The marble rendzinas, though distinctive, form only a relatively small part of the soils of the botanically significant region of Upper Teesdale. The brown earths, brown calcareous soils and the various gleys developed on drift and other parent materials are also important.

Bedrock–Soil–Flora Association

The combination of lower Carboniferous clear water limestone, late Carboniferous Earth movements and the injection of the Whin Sill produced coarse grained crystalline marble in Upper Teesdale. Tertiary and recent erosion with the Quaternary glaciation exposed this unusual bedrock at the surface. Rendzinas developed on outcropping marble by soil forming processes. A geological setting of this type is unknown outside Upper Teesdale in Britain and comparable rendzinas are similarly restricted. In the vicinity of this narrow geological and pedological setting the Teesdale flora has survived since shortly after the end of the Quaternary glaciation. It is our contention that the survival of the relict flora in association with unique geology and soils is not coincidental. The inherent instability and excessive drainage of the calcite sand soils have provided a continuous series of precarious habitats suitable for the survival of the alpine plants. In the vicinity of these soils elements of the flora have colonized restricted adjacent regions of differing soil type giving the plant distribution found today. Other factors have clearly played their part in sustaining the flora over the period of about 10,000 years. Two factors are particularly noteworthy; first, the severe climate of the Teesdale fells provides a suitable environment, and second, continuous grazing of the small areas of limestone grassland from prehistoric times[12] to the present day has tended to maintain the required more open habitats.

We thank Drs W. A. Clark, A. W. Davison, J. Turner and D. F. Ball who have read the manuscript and offered helpful advice. This research forms part of a survey of Upper

Teesdale supported by the Natural Environment Research Council.

Transitive Inferences and Memory in Young Children

P. E. BRYANT
Department of Experimental Psychology, University of Oxford

T. TRABASSO
Department of Psychology, Princeton University

Contrary to the conclusions of Piaget, young children can make transitive inferences if precautions are taken to prevent deficits of memory from being confused with inferential deficits.

FOR some time, it has been believed that young children are unable to form transitive inferences about quantity until they pass the stage of logical preoperations at about 7 yr old[1,2]. This argument has been very widely accepted[3,4]. Piaget and his colleagues propose that the young child cannot infer, for example, that $A > C$ from the information that $A > B$ and $B > C$. They assert that the child is unable to coordinate the first two, separate items of information in order to reach the correct inferential conclusion about A and C. If true, this claim has important educational implications, for a child who cannot combine this information must also be unable to understand the most elementary principles of measurement.

We report two experiments which show that the claim is unjustified. The experiments demonstrate that 4 yr old children can make transitive inferences about quantity, provided that they can remember the items of information which they are asked to combine.

One must ensure that the child has retained the comparisons which he has to combine, if one is to infer whether or not he can make transitive inferences. Otherwise, an error might simply be due to a failure in memory and have nothing to do with inferential ability. Yet experiments in which it is reported that children cannot make inferential judgments lack this elementary precaution. One can control for forgetting by taking two precautions. First, teach the child the initial comparisons ($A > B$ and $B > C$) very thoroughly. Second, test for memory of these comparisons at the same time as one asks the inferential question about A and C. The first precaution ensures retention of the initial comparisons and the second checks for this retention during the inferential problem.

We found it necessary to introduce another control in our experiments. This was against the transfer of "absolute" responses. The general procedure in prior experiments has been to use three quantities (A, B and C). If only three are used, the correct response to the two extreme quantities must be the same in both the inferential problem and in the initial direct comparisons. The quantity A is the "larger" when compared with B, and C is the "smaller" when compared with B, in the initial direct comparisons. Yet "larger" is the correct response to A and "smaller" is the correct response to C in the inferential AC comparisons. Thus a child who produces the correct response when asked the AC question may do so by parroting a verbal label picked up during the initial comparisons, and not, as has always been assumed, by making a genuine inference through the combination of two separate comparisons.

The correct control is to introduce more stimuli and thus more direct comparisons. If there are as many as five stimuli (in descending order of size they are A, B, C, D and E) four initial direct comparisons are possible, $A > B$, $B > C$, $C > D$, and $D > E$. Note that B, C, and D all feature in two of these comparisons and that each of them is the larger in one comparison and the smaller in the other. This means that no one absolute response can be transferred to any one of these three quantities, and it therefore follows that the crucial transitive comparison will be between B and D. This indirect comparison cannot be solved by transfer of absolute responses, since B and D were both larger and smaller in the initial direct comparisons.

Our experiments thus involved first a thorough training period with four direct comparisons, followed by a test period in which the children were tested for their ability to make transitive judgments *and* to remember the initial comparisons. In the first experiment, sixty children in three age groups of twenty each participated. The mean ages of the groups were

4.5, 5.6, and 6.7 yr respectively. The youngest group came from a local nursery school and the older groups from two local infants' schools.

The training and testing materials were identical. Five coloured wooden rods, each of a different length and colour, were used. The lengths were coloured differently in order that they could be identified and remembered. Thus the child learned, for example, that blue was larger than red and red larger than green. The colours were red, white, yellow, blue and green, and the lengths were 3, 4, 5, 6 and 7 inches. The particular colour–length combinations differed from child to child and were counterbalanced within each age group.

The rods were presented in pairs throughout the experiment. The pairs were always presented in such a way that each rod protruded from the top of a container by one inch. The equal protrusion was achieved by sinking bores of different lengths in the container box. This kind of presentation forced the child to use the colour differences in making a choice between different lengths.

In the initial training, each trial consisted of showing the child a pair of rods of different colours, each rod protruding one inch from the top of the box. The child was asked to indicate which rod was the "taller" or the "shorter" ("big" and "little" were the terms used with the youngest group, as they were more easily understood). When the child made his choice the experimenter drew out the rods and held them perpendicular to the table, so that the child could compare lengths directly. This was the feedback for the choices in the direct comparisons, which enabled him to learn to make the correct choice. The question asked (taller and shorter) and the positions of the rods (left and right) were varied in an irregular order from trial to trial.

The training was divided into two phases. In the first, the four comparisons, $A > B$, $B > C$, $C > D$, and $D > E$, were trained separately and in order from either the tallest to the shortest or vice versa; half of the children in each group were trained with each order. Each of the pairs was learned to a criterion of eight out of ten successful choices. In the second phase which followed immediately, all four pairs were presented in a random order on different trials. This interweaving continued until each child responded correctly to six successive presentations of each pair.

Testing followed immediately after the completion of the second training phase. The testing procedure was the same except that no feedback at all was given, that is, the lengths were not shown after a choice. Each child was tested four times on every one of the ten possible pairs of colours. These ten included the four, initial (direct) comparisons, and six, new, transitive (indirect) comparisons. The order in which the pairs were tested was random and varied between children. The type of questions and the position of the rods in each pair varied irregularly as in training.

All groups learned the initial (direct) comparisons rapidly. In the first phase of the training there seemed to be no age differences in speed of learning. In the second phase, however, the 4 yr old children made more errors than the other two age groups who were not significantly different from each other.

The test results are summarized in Table 1, which gives the average probability of a correct response on each pair of colours for each age group. The main diagonal cell entries (A, B: B, C: C, D: D, E) of each subtable in Table 1 show the correct choice probabilities for the initial direct comparisons. The top row and the right column off-diagonal entries (A, C: A, D: A, E: B, E: and C, E) are those for transitive tests where one or both of the rods included one of the end points, which were always either larger (A) or smaller (B). (These transitive comparisons may have been susceptible to the transfer of absolute responses.) The critical entry is the off-diagonal B, D pair, in which each rod had been both larger and smaller in the initial comparisons. The importance of this cell is stressed.

The evidence for transitivity is impressive at all age levels. All the transitive comparisons (AC, AD, AE, BD, DE, and CE) were well above chance level, since the upper 99% confidence bound on the hypothesis of chance is 0.65 with a sample of $n=20$. Turning back to the crucial BD comparison it should be noted that children at all three age levels were able to make genuine transitive inferences very well.

It should also be noted that the BD scores were consistently the lowest of all ten comparisons. Of particular interest is the fact that the children seemed to perform at a lower level with the BD comparisons than with BC or CD comparisons, and yet these last two provide the information on which the transitive BD judgment must be based. This conclusion is supported by an analysis of variance of the errors on these three comparisons, which produced a significant difference between pairs (F3.3%, d.f.2,114, $P<0.05$) and no interaction with age. Thus our conclusion from the first experiment was that young children can make genuine transitive inferences extremely effectively, but not perfectly. The reason for less than perfect inference is discussed later.

Table 1 Probability of Correct Choices on Tests for Transitivity and Retention (Experiment 1)

Stimulus	B	C	D		E
4 yr old children					
A	0.96	0.96	0.93		0.98
B	—	0.92	0.78 †	(0.83) *	0.92
C	—	—	0.90		0.94
D	—	—	—		0.91
5 yr old children					
A	1.00	0.96	1.00		0.98
B	—	0.86	0.88 †	(0.80) *	1.00
C	—	—	0.92		1.00
D	—	—	—		1.00
6 yr old children					
A	0.99	0.99	1.00		1.00
B	—	0.94	0.92 †	(0.92) *	0.99
C	—	—	0.98		1.00
D	—	—	—		1.00

* Predicted.
† Critical entry.

There is, however, one possible objection to our conclusion. In the training phase we showed the children the full length of the rods when we gave them feedback at the end of each trial. It is possible that the children solved the BD transitive question not by making a genuine transitive inference but simply by remembering that B was 6 inches and D was 4 inches. Such a solution to the problem is not an inferential one, and although we did not think that this kind of solution was likely, nevertheless we did not exclude its possibility in the first experiment.

We therefore carried out a second experiment on twenty-five 4 yr old and twenty-five 5 yr old children, in which our procedure was exactly the same as in the first experiment, except that we eliminated visual feedback during the training session. Instead of being shown which of the two rods was longer at the end of each training trial, the children were simply told which was the longer and which the shorter. The rods were never displayed completely until the whole experiment was finished.

The test results for this experiment are given in Table 2, which shows that the removal of visual feedback had no effect on children's ability to make transitive comparisons. Once again performance on all transitive comparisons was well above chance. The performance of both age groups was as good in the BD comparison in this experiment as the performance of the equivalent age groups in the first experiment. Again, however, the BD scores were somewhat lower than the BC and CD scores. We analysed the scores of the 4 and 5 yr olds on these three comparisons in the two experiments

Table 2 Probability of Correct Choices on Tests for Transitivity and Retention (Experiment 2)

Stimulus	B	C	D		E
4 yr old children					
A	0.98	0.98	0.93		0.97
B	—	0.89	0.82 †	(0.77) *	0.90
C	—	—	0.87		0.88
D	—	—	—		0.94
5 yr old children					
A	0.98	0.92	0.95		0.97
B	—	0.87	0.85 †	(0.85) *	0.98
C	—	—	0.97		0.95
D	—	—	—		0.98

* Predicted.
† Critical entry.

together, and again found a significant difference between pairs ($F3.89$, d.f.2,172, $P<0.05$). There was no interaction with age or with experiments. Thus in both experiments, children's transitivity, though considerable, was not perfect.

We shall now argue that the lower performance on the crucial BD pairs is not due to a failure to make inferences but to a failure of retention of the information contained in the initial comparisons. Let $P_{b,c}$ and $P_{c,d}$ be the respective probabilities of recalling the information on the BC and CD pairs. Assume that the recall of these information units is independent. Then the probability of making a correct inference on the BD test ($P_{b,d}$) is the probability of jointly recalling the information for each of the training pairs. Since these events are independent, their probabilities multiply; that is, $P_{b,d}=P_{b,c}\times P_{c,d}$.

These assumptions were tested by multiplying the observed probabilities for the BC and CD tests for each subtable of Tables 1 and 2. The predicted $P_{b,d}$ is shown in parentheses. It can be seen that these predictions are reasonably close to the observed values. Hence, the lower performance on the BD tests may be attributed to a failure in memory rather than to inferential difficulty.

This last experiment conclusively demonstrates that very young children are able to make transitive inferences extremely effectively. They can combine separate quantity judgments very well and they can do so at a far younger age than has generally been assumed. This is a conclusion which has practical as well as theoretical importance.

Optimum *P*% Library of Scientific Periodicals

B. C. BROOKES

School of Library Archive and Information Studies, University College London, Gower Street, London WC1E 6BT

A quantitative method is described for finding the optimum percentage of periodicals for a library in a given field. The appearance of new journals is apparently counterbalanced by the disappearance of the old.

By applying two empirical laws of informatics it is now possible to design the most compact selection of scientific periodicals to cover any specified percentage $P\%$, of the total periodical coverage of any well defined scientific subject. The two laws are the Bradford law of scatter and the negative exponential law of obsolescence.

Ideal and Practical Totalities

If all scientific periodicals are supposed to be arranged in order of decreasing productivity of papers relevant to some specified subject S, an ordered linear array which can be subdivided into three exclusive sets is obtained.

The set S_1 consists of all periodicals which contribute an average of at least r papers/yr which are relevant to S. The set S_2 consists of those periodicals which have contributed some papers relevant to S but with an average productivity which is less than r papers/yr. The set S_3 consists of those scientific periodicals which have not yet contributed papers relevant to S and are practically certain not to (Fig. 1).

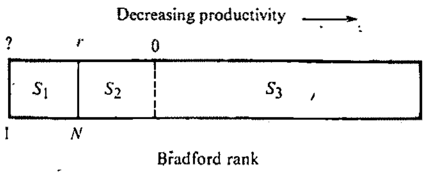

Fig. 1 The three sub-sets of periodicals.

From the point of view of a scientist interested only in the subject S, the periodicals of the set S_3 need not be identified. The periodicals of S_2 are identifiable by the fact that they have contributed some relevant papers: they must be regarded as candidates for inclusion in S_1. The periodicals of set S_1 contain almost all the literature relevant to S if r is made small enough. To make quantitative analysis possible, some numerical value has to be assigned to r.

Bradford observed[1] that if the periodicals which contribute papers relevant to any well defined scientific subject S are arranged in decreasing order of productivity and ranked 1, 2, 3, . . . , then the periodical ranks begin with a very productive "nuclear" zone (of ranks 1 to c, where c may be any number from 3 upwards and which increases with the generality of the subject) followed by a long tail of steadily less productive periodicals.

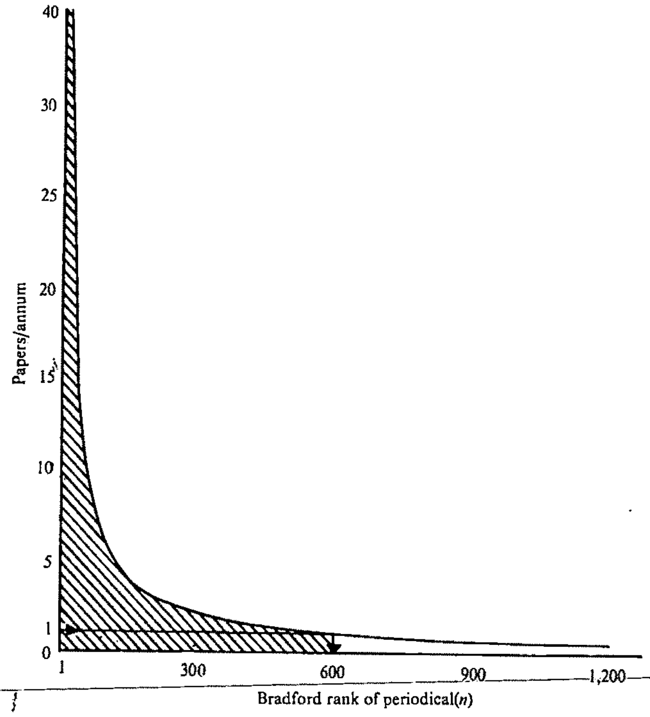

Fig. 2 The stipulated 100% totality (linear scales).

It has been shown[2] that the total number of relevant papers contributed by the periodicals of rank 1 to n is given by

$$R(n) = N \log_e n/s, \ (n \geqslant c) \tag{1}$$

where N is the number of periodicals which contribute an average of at least 1 paper/yr and s (>1) is a constant characteristic of the subject. It follows that the periodical of rank n contributes N/n relevant papers/yr. The total number of papers contributed by set S_1 will therefore be

$$R(N/r) = N \log_e N/rs \tag{2}$$

When $n \leqslant N$ or $r \geqslant 1$, the contributing periodicals can all be identified without difficulty. When $n > N$, the periodicals contribute only occasionally and apparently at random.

For the purposes of this analysis it is therefore stipulated that the practical annual totality of papers relevant to S be that contributed by the periodicals ranked 1 to N, so that $r = 1$. This total, henceforward regarded as the 100% totality, is given by

$$R(N) = N \log_e N/s \tag{3}$$

For example, if $N = 600$, $s = 1.5$, then

$$R(N) = 600 \log_e 400 = 600 \times 5.99$$
$$\approx 3{,}600$$

Admittedly, this totality is arbitrarily defined; some further papers will be contributed by periodicals outside the set S_1. But any other definition of totality which is also quantifiable would be open to similar criticism. The difficulty is illustrated by Fig. 2 which shows how the annual productivity decreases as n increases up to and beyond N for the case in which $N = 600$, $s = 1.5$. The practical totality proposed is indicated by the shaded area.

Obsolescence

It is known that the immediate or scientific usage of scientific periodicals declines with the age of the periodical volumes. Strictly, this decline conforms closely with a negative exponential law but, in practice, because reference is usually given to the year of publication, it is much more convenient to use instead the geometric distribution:

$$p(t) = (1-a)a^{t-1}, \ (1 < t < \infty) \tag{4}$$

where $p(t)$ is the probability of reference to an issue of the periodical of age t years and a is a constant characteristic of the literature and of the nature of its usage.

It will be assumed that a is constant for all values of t. For $a < 1$, the series

$$1 + a + a^2 + \ldots a^{t-1} + \ldots$$

converges to the sum $1/(1-a)$ as $t \to \infty$. If R references are made to a given periodical in a given library context during its first year of life, then aR references can be expected during its second year, a^2R references during its third year and so on. It is therefore possible to estimate the total number of references that will be made to it during its (infinite) lifetime. This total will be

$$R(1 + a + a^2 + \ldots a^{t-1} + \ldots) = R/(1-a) \tag{5}$$

If the issue of the periodical is already t years old, then the number of further references to it that can be expected is given by

$$R(a^t + a^{t+1} + a^{t+2} + \ldots)$$
$$= Ra^t(1 + t + t^2 + \ldots) \tag{6}$$
$$= Ra^t/(1-a)$$

which reduces to (5) when $t = 0$.

Within the given library context, expression (5) can be called the total utility of a periodical volume which has just been published; it will be denoted by $U(O)$. Its remaining utility at age t is given by (6) and can be denoted by $U(t)$. We then have

$$U(t) = Ra^t/(1-a) = a^t \ U(O) \tag{7}$$

For calculations on utilities the most convenient technique is to draw the graph of

$$a^t = U(t)/U(O) \tag{8}$$

using a logarithmic scale for $U(t)/U(O)$ (as a fraction or as a percentage) and a linear scale for t. Values of t corresponding to any fraction, for a given value of a, can then be read directly from the straight line graph, and vice versa.

The sum of the geometric series, $1/(1-a)$, decreases as a, the annual ageing factor, decreases; that is, short lived periodicals have a smaller total utility than periodicals in which interest declines more slowly. The factor $1/(1-a)$, which arises frequently in the analysis of obsolescence, will henceforward be called the utility factor of the periodicals and be denoted by u.

Application to a Bradford Periodical Set

It will now be assumed that all the relevant papers in the current issues of the set of N periodicals which constitute the totality are of equal significance. (It seems likely that the papers published in the periodicals of the nuclear zone are, on average, of greater significance than those in the more peripheral zones but this issue awaits empirical analysis.)

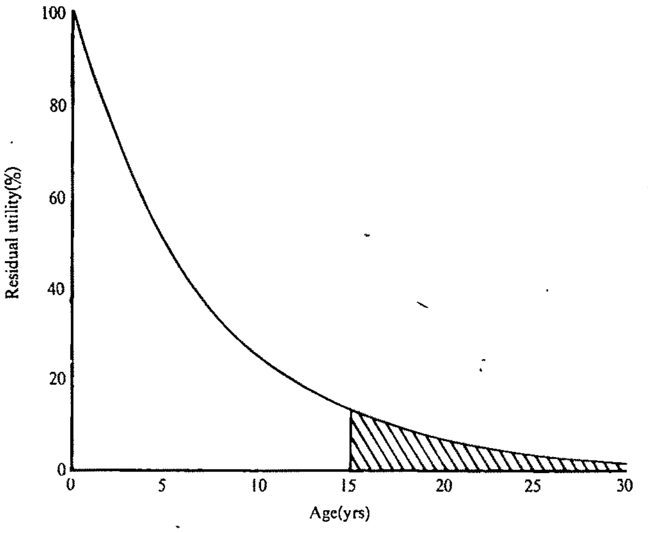

Fig. 3 The residual utility (linear scales).

Consider the utility of the periodical of rank n in a Bradford set. This periodical will have an annual average of N/n relevant papers and so the distribution of utilities over the successive years of its life from $t=0$ to $t=1, 2, \ldots$ is given by the series

$$N/n\,(1+a+a^2+\ \ldots\ a^{t-1}+\ \ldots\ )\doteq Nu/n \qquad (9)$$

So its initial utility is N/n (10*a*)

its utility at age t is $N\ a^{t-1}/n$ (10*b*)

its total utility is Nu/n (10*c*)

and its residual utility after t yr is Nua^t/n (10*d*)

(These measures are relative rather than absolute, but it is not necessary to multiply each by the same constant when only comparisons within a given library context are being made.) We have so far regarded the series (9) as expressing the declining utility of a single volume of the periodical as it ages from $t=0$ to $t=1, 2, 3, \ldots$ and so on (Fig. 3). But it can also be regarded as expressing the declining utilities of the ageing volumes of the periodical in its present complete run.

The sum of all the relevant papers in the Bradford set is given by

$$R(N)=N\log N/s$$

so that, for the complete Bradford set, the analogous utility measures are

initial utility is $R(N)=N\log N/s$ (11*a*)

utility at age t is $R(N)a^{t-1}=Na^{t-1}\log N/s$ (11*b*)

total utility is $R(N)u=uN\log N/s$ (11*c*)

and residual utility after t years is $R(N)\,ua^t=uNa^t\log N/s$ (11*d*)

We can now consider techniques of selecting $P\%$ of the total utility of a complete Bradford set of periodicals.

Some $P\%$ Solutions

There is an infinity of ways of selecting $P\%$ from the 100% totality. The simplest technique is to cut the complete Bradford set of N periodicals to the smaller set ranked $1, 2, \ldots M$, that is, to the M most productive periodicals. In this case M would be given by

$$N\log M/s=N\log N/s\times P/100$$

so that

$$M/s=(N/s)^{P/100} \qquad (12)$$

For $N=600$, $s=1.5$, $P=50\%$ and 75%, this result yields $M=30$ for $p=50\%$ and $M=90$ for 75% (Fig. 4).

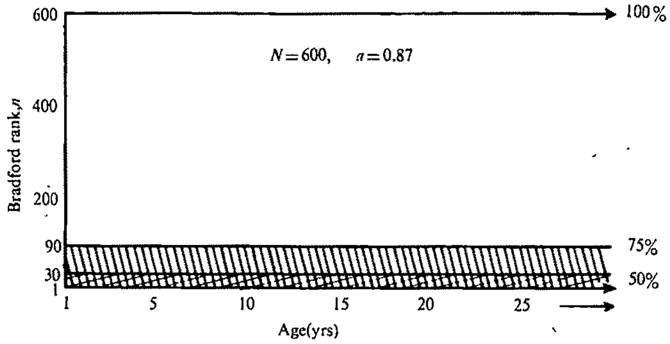

Fig. 4 The 50% and 75% "Bradford cut" solutions.

The solution reduces the expenditure on periodicals to the minimum for any specified value of P, but it has the disadvantage of leaving the shelves still occupied by the long little-used tails of the periodicals remaining so that the mean utility per metre shelf space is still low.

A second "cross cut" solution is to leave equal runs (in terms of years) on the shelves but to discard the ageing tails at the age given by

$$a^t=\frac{\text{discard utility}}{\text{initial utility}}=(1-P/100)=f \qquad (13)$$

For $a=0.87$ (half-life$=5.0$ yr) we have for $a^t=0.5$, $t=5.0$ yr and, for $a^t=0.75$, $t=10$ yr (Fig. 5).

Such solutions have the advantage of providing 100% coverage of papers published within some specified age limit, but the most productive periodicals are thus discarded when their residual utilities are still very high compared with the initial utilities of the peripheral periodicals.

A third solution, the "contour cut", is to discard tails of equal residual utility so that all the volumes remaining on the shelves have utilities above this critical discard level and yet give an overall $P\%$ coverage. This technique implies that

Table 1 Estimates of Shelf Space Required

Method	Bradford cut	Cross cut	Contour cut
50%	1,500	3,000	556
75%	4,500	6,000	2,570

Bradford set: $N=600$, $s=1.5$, $a=0.87$.

Shelf space is estimated in "periodical years", 100% required 30,000 periodical years for a 50 yr life.

periodicals of low initial utility will have much shorter runs than the more productive periodicals.

Consider the total loss of utility if the discard utility is equal to the initial utility of the periodical of rank M. We then have a discard utility level of N/M and for any periodical of rank n, where $c \leqslant n \leqslant M$, we have the age of discard, t, given by

$$a^t = \frac{\text{discard utility}}{\text{initial utility}} = \frac{N/M}{N/n} = \frac{n}{M} \qquad (14)$$

The corresponding value of t can be read from the graph of a^t. The residual utility of the nth periodical at discard, using (10d) and (14), will therefore be

$$Nua^t/n = Nun/nM = Nu/M \qquad (15)$$

Each of the M periodicals is, by this technique, discarding equal utilities, so the total utility thus discarded is Nu. Moreover, because the periodicals of rank $(M+1)$ to N have been discarded completely, we have the proportional loss of utility from the 100% totality, using (11c), given by

$$\frac{Nu + uN \log N/s - uN \log M/s}{uN \log N/s} = \frac{1 + \log N/M}{\log N/s} = f \quad (16)$$

from which the value of M for any specified value of f can be found. For $f=0.5$ and 0.25 and for the same numerical data used above, 50% utility would be provided by the most productive eighty-one periodicals and 75% utility by the most productive 364 periodicals when all are discarded as they decline to the same discard utility contours (Fig. 6). The technique is easy to apply because, when the contours are mapped on a graph on which n is logarithmic and t is linear, they appear as parallel straight lines for $c \leqslant n \leqslant N$.

Table 2 Costs per Relevant Paper

Range of set acquired	Yield of relevant papers per annum	Relative cost paper/yr
1–75	2,350	1
1–150	2,760	1.70
1–300	3,180	2.97
1–450	3,420	4.12
1–600	3,600	5.22

Bradford set: $N=600$, $s=1.5$.

The advantage of this contouring technique is that it provides the most compact solution of the P% library but costs more in the buying of periodicals than the Bradford cut method. (In practice it may be convenient or economical to use some hybrid form of two of these solutions but if the hybridization is rationally planned it is possible to estimate the corresponding value of P for any compromise that may be decided on or to design the hybrid to conform with any specified value of P.)

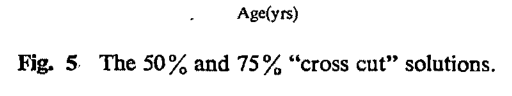

Fig. 5 The 50% and 75% "cross cut" solutions.

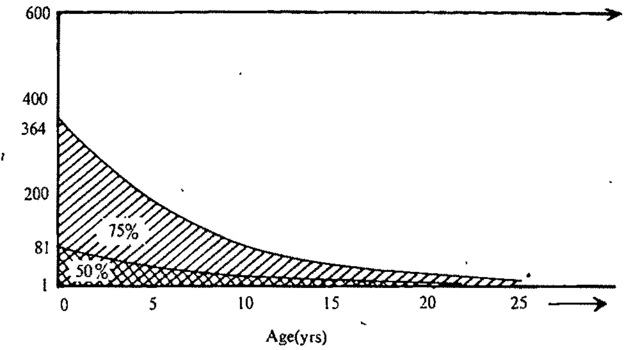

Fig. 6 The 50% and 75% "contour cut" solutions.

Estimates of the shelf space demanded by each of the three solutions, in terms of "periodical years", are given in Table 1. In these estimates a complete back run is reckoned at 50 periodical years so that the 100% totality would require 30,000 periodical years. It can be seen that the contour method offers the most compact solutions.

Effects of Growth

The cost per relevant paper acquired by buying periodicals increases steadily as the range of the periodicals ranked 1 to n of a Bradford set increases (Table 2). It is therefore uneconomic to attempt 100% coverage especially if the particular science library is backed by some regional or national library serving many science libraries from which it can borrow periodicals, acquire photocopies or particular papers or receive suitable video transmissions. The cut-off point at which it becomes more economic to borrow than to buy[3] then determines the value of P.

I have assumed that the literature of the particular scientific subject S grows uniformly year by year and that it conforms closely with the empirical laws applied. But even if these conditions are not fulfilled, the principles underlying the techniques can still be applied though more laborious graphical methods may have to be adopted. In practice, too, the Bradford set selected in any one year is also liable to change as new periodicals appear, as some die in their tracks and as others change the focus of their scientific interest. So once the required P% library has been established it will need regular review and revision. If the rate of growth of the literature is increasing, then the value of a can be expected to decrease from year to year. But increase in the rate of growth of the literature is more likely to arise from an increase in the number of scientific workers than from an increase in their output of scientific papers. An increase in the number of scientists working in the subject increases the utility of all the literature they depend on. And so the effects of the two kinds of growth act in opposite directions on the magnitude of a. It can be shown that if the two rates of increase are equal, then the value of a is unchanged[4].

It is interesting that the P% library designed by the contour technique discards, year by year, as many annual volumes as it acquires. The "information explosion" becomes less alarming if it is appreciated that the "explosion" of new literature is almost exactly counterbalanced by the discarding of the old. But the librarian is conservative; he has yet to learn how to be as ruthless as his scientific colleagues in the art of discarding the obsolete.

Solar Proton Medium Flux Constancy over a Million Years

THE data of cosmogenic radionuclide activity measurements in lunar material from the Apollo 11 and 12 missions have now been published[1-8]. Unfortunately, the data concern chiefly the measurements of medium radioactivity of whole rock (by non-destructive gamma-spectrometry) or large volume samples (by radiochemical methods). The data provide no way to determine the overall depth distribution gradient of radionuclides, produced by galactic and solar cosmic rays, and so no information can be extracted about the intensity of cosmic rays. But ref. 1 describes how the radioactivities of some radionuclides have been measured as a function of depth in lunar sample 10,017. By analysing these data we have drawn a conclusion about possible constancy of solar proton medium flux for the last million years.

For our purpose the calculation of the depth distribution of cosmogenic isotopes in the surface layer of the Moon has been fulfilled, which allows accurate interpretation of the measurements. The calculation enables us to determine the distribution with depth of primary cosmic ray and secondary nuclear-active particles as well as the distributions of cosmogenic radionuclides[9-11]. The efficiency of the method has been proved by numerous calculations of radioactivities in meteorites. Our calculations have been carried out for a large body ($d \ll R$) with composition similar to that of the lunar crystalline rock B/17-33/ (ref. 6), for which depth radioactivity was measured[1]. The production cross sections of radionuclides from the different elements in the energy range 0.001 to 28 GeV have been taken from the experimental data of ref. 12. Unknown cross sections have been resolved from formulae (1) and (2) (*vide infra*) which link, by the ratios of Rudstam coefficients[13], unknown production cross sections of an isotope from a target with experimental production cross sections of this isotope from other targets

$$\sigma_i^{\mathrm{I}}(A_i Z_i) = \frac{K(A^{\mathrm{I}})}{K(A^{\mathrm{II}})} \exp\{[P(A^{\mathrm{I}}) - P(A^{\mathrm{II}})]A_i\}\, \sigma_i^{\mathrm{II}}(A_i Z_i)^{\mathrm{exper.}} \tag{1}$$

where I, II are the targets and *i*, *j* the isotopes, or, with that of other isotopes from the same target[14]

$$\sigma(A_i Z_i) = \exp[P(A_i - A_j) - R_i(Z_i - S A_i + T A_i^2)^{3/2} + R_j(Z_j - S A_j + T A_j^2)^{3/2}]\, \sigma(A_j Z_j)^{\mathrm{exper.}} \tag{2}$$

Thus, the same cross sections can be calculated from (1) and from (2) using different experimental data. The cross sections determined in this way were weighted according to the integral cosmic ray spectra and composition of the rock. The intensity and spectrum of the galactic cosmic rays were determined from the measurements in the stratosphere for the period 1958 to 1970 (refs. 15 and 16). The spectrum of solar protons with energy >20 MeV has been given in ref. 17, together with depth distributions of solar protons and secondary neutrons in the lunar surface layer. Because of the lack of data for the medium solar proton intensity over long periods of time we believe it is best for our purpose—to compare cosmic ray intensity for different time intervals—to determine the quantity of medium intensity solar protons by extrapolation of the measured activity data of one of the radionuclides (for example ^{22}Na) in lunar rock. Further calculations of the depth distributions of other radionuclides with different half lives, using the same value of solar proton intensity, will lead by comparison with measured activities of these isotopes to an estimate of the constancy of the solar proton flux.

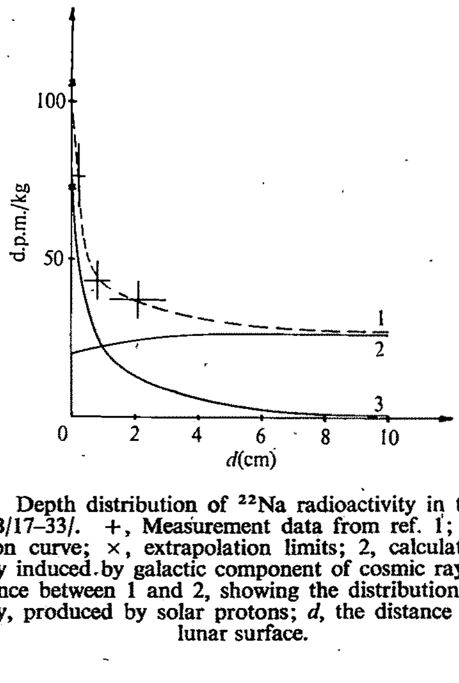

Fig. 1 Depth distribution of ^{22}Na radioactivity in the lunar rock B/17-33/. +, Measurement data from ref. 1; 1, extrapolation curve; ×, extrapolation limits; 2, calculated ^{22}Na activity induced by galactic component of cosmic rays; 3, the difference between 1 and 2, showing the distribution of ^{22}Na activity, produced by solar protons; *d*, the distance from the lunar surface.

In Fig. 1 the ^{22}Na activity measured as a function of depth[1] is plotted, with experimental errors in the depth ranges marked. Extrapolation of curve 1 intercepts the ordinate at 96 d.p.m. kg^{-1} with $\left\{\begin{matrix}+10\%\\-25\%\end{matrix}\right.$ error (extrapolation limits marked by crosses on ordinate). Curve 2 shows our calculated depth distribution of ^{22}Na produced by the galactic component of cosmic ray and secondary nuclear-active particles. The difference between these curves (curve 3) shows accumulation of ^{22}Na by solar proton and secondary neutron bombardment. According to ref. 17 the secondary neutron flux is three orders of magnitude smaller than incident solar proton flux on the lunar surface, so that the interception point of curve 3 with the ordinate defines the activity induced by solar protons with intensity $2.46^{+0.44}_{-0.74}$ protons cm^{-2} s^{-1} sterad^{-1} (that is, $\left\{\begin{matrix}+18\%\\-30\%\end{matrix}\right.$ error). This is the medium solar proton flux for 4 yr from 1966 to 1969 (1.5 $T_{1/2} \sim 4$ yr for ^{22}Na). With this value of medium intensity of solar protons the activities of other

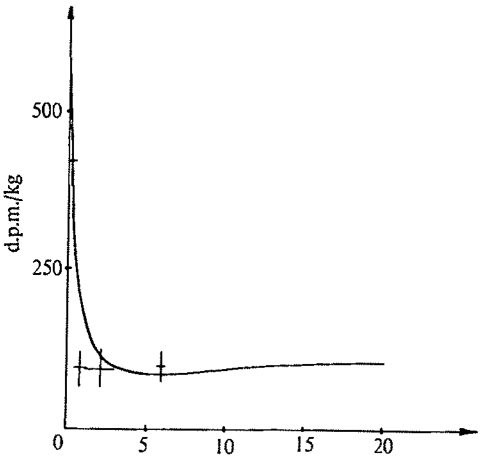

Fig. 2 Depth distribution of ^{55}Fe radioactivity in the rock B/17–33/.

long lived radionuclides in lunar rock B/17–33 have been calculated. In Fig. 2 the curve of calculated ^{55}Fe activity as a function of depth is plotted, with measured points from ref. 1. (The ^{55}Fe half life is the same as that of ^{22}Na.) In Fig. 3 the radioactivity data of ^{26}Al, with half life 7.4×10^5 yr, are plotted. The agreement between calculated (curve 1) and measured depth change of ^{26}Al activity is good. Extrapolation over ^{26}Al measured data, in the same way as for ^{22}Na above, gives medium solar proton intensity $2.46^{+0.34}_{-0.54}$ protons cm^{-2} s^{-1} sterad^{-1} (that is, $\begin{cases}+14\% \\ -26\%\end{cases}$ error). We have also calculated the depth distributions of ^{26}Al activity induced by solar protons with twice smaller intensity (curve 2) and with twice greater intensity (curve 3). For depth $d > 4$ cm all three curves draw nearer because of the fall in solar proton flux, but the corresponding ^{26}Al activities on the surface lie far outside the limits of possible extrapolation.

It follows from this analysis that at least within ~30% error we can say that the mean intensity of solar cosmic rays with the energy >20 MeV has been constant for the last million years at about $31.1^{+5.6}_{-9.4}$ protons cm^{-2} s^{-1}. This conclusion is confirmed by calculations of radioactivities of ^{53}Mn ($T_{1/2} = 2 \times 10^6$ yr) and ^{54}Mn ($T_{1/2} = 303$ d).

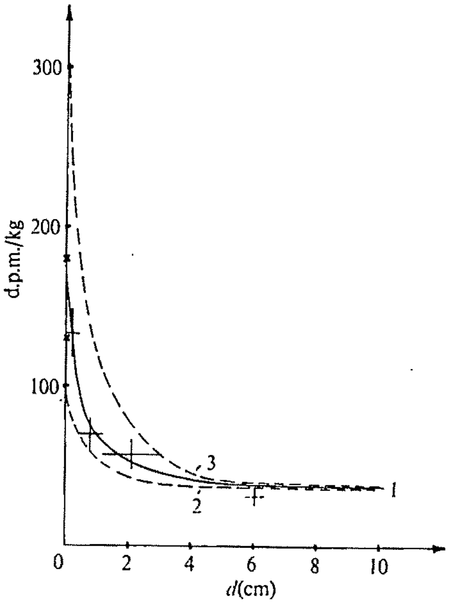

Fig. 3 Depth distribution of ^{26}Al in the rock B/17–33/. +, Measurement data from ref. 1; 1, ^{26}Al activity calculated using the medium solar proton intensity 31.1 protons cm^{-2} s^{-1}; 2, depth distribution of ^{26}Al, calculated with twice smaller solar proton flux; 3, ^{26}Al distribution, calculated with twice greater solar proton flux; ×, the limits of possible extrapolation.

Extragalactic Faraday Rotation

IN three very important and groundbreaking papers, Sofue, Fujimoto and Kawabata[1], Kawabata *et al.*[2], and Reinhardt and Thiel[3] call attention to evidence which indicates that Faraday rotation is taking place in space outside our own Galaxy. Essentially they show that above low galactic latitudes, where material in the disk of our own Galaxy is known to produce Faraday rotation, extragalactic radio sources exhibit Faraday rotations which generally increase with the redshift of the source, and that these rotations behave similarly in certain regions of the sky.

They attribute this extragalactic Faraday rotation to a metagalactic magnetic field which is ordered on the scale of the observable universe (the scale observable on the assumption that the redshifts of the quasars are cosmological). It seems to me, however, reasoning in analogy with our own Galaxy, that this latter model is not the most likely one with which to explain the extragalactic Faraday rotations. It would not, for example, be logical to look to the low-density polar regions and possible ordered magnetic field in our own Galaxy for Faraday rotation. Instead we look to the plane where we know there are concentrations of ionized matter and magnetic

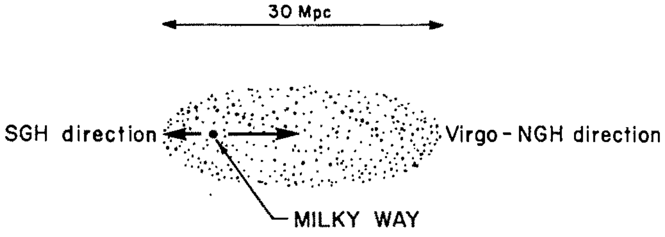

Fig. 1 Schematic cross-section of the local supercluster showing location of Local Group and approximate dimensions.

field in the form of gas, H II regions, and spiral arms. In fact, this is where the galactic Faraday rotation is observed.

When we look outside our own Galaxy, however, we see something analogous in the local supercluster of galaxies as outlined by de Vaucouleurs[4]. In that supercluster there is a concentration of galaxies in the supergalactic plane. Those galaxies represent the concentrations of ionized matter and magnetic field which we know about—and it is here that the authors of refs. 1–3 find the maximum extragalactic Faraday rotation.

That direction of maximum Faraday rotation was designated originally by Sofue *et al.* as $l^{\mathrm{II}}=100°$, $b^{\mathrm{II}}=-30°$ and the opposite direction in the sky $l^{\mathrm{II}}=280°$, $b^{\mathrm{II}}=30°$. In the latest paper by Kawabata *et al.*, the direction is designated as $l^{\mathrm{II}}=115°$, $b^{\mathrm{II}}=-5°$. Perhaps this difference is an indication of the uncertainty of the determination. In any case, as Sakashita and Kaneko pointed out[2], this direction lies in the plane of the supercluster. It is close to the direction of the Virgo cluster $l^{\mathrm{II}}=280$ to 300, $b^{\mathrm{II}}=+50$ to $+70$, which marks the approximate centre of the local supercluster as seen from our own Galaxy.

In order to test further the alternatives represented by the two models, we should indicate that the local supercluster is supposed to be a flattened system of galaxies and clusters of galaxies about 30 Mpc in diameter, as shown in Fig. 1. Our own Local Group of galaxies is located somewhere out near the edge, so that we see the bulk of the supercluster in the direction of Virgo, but there is also a lesser amount of supercluster which we look out through in the opposite direction.

$\langle\lvert RM\rvert\rangle=21.0\pm2.4$ (p.e.)					

Data from Reinhardt and Thiel, Table 1. (Note their value of b^{II} for 3C390 should be changed from +60 to +6.) 3C273 is excluded from this table as anomalous.

Table 1 shows that the Faraday rotations in the north galactic hemisphere (the general direction of the centre of the supercluster) average about twice the absolute value of Faraday rotations in the direction of the south galactic hemisphere (opposite the centre of the supercluster). Another interesting result is that the mean value of the redshifts of these quasars and allied objects is about 0.1 greater in the supercluster centre direction as opposed to the supercluster anticentre direction. I have previously suggested that most quasars and quasarlike compact galaxies are at distances closer than their redshifts would indicate[5] and are, in fact, generally members of the Local Group and local supercluster. In that case we would expect more distant quasars, on the average, in the direction of the bulk of the supercluster and fewer lower-redshift objects in the anticentre direction. This kind of distribution would be expected to give Faraday rotation from material within the local supercluster roughly as indicated in Table 1.

Finally, it is necessary to test the increase in the mean absolute value of the Faraday rotation as a function of the redshift of the source. None of the previous papers have shown such a plot, but Fig. 2 shows the Faraday rotations for high-latitude radio sources as a function of redshift. Although there is considerable scatter, it is clear that the sources with very low redshifts have $\langle\lvert RM\rvert\rangle\sim10$ rad/m^2, the sources with $z\sim0.5$ have $\langle\lvert RM\rvert\rangle$ between 10 and 20, and the sources with $z\sim1.0$ have $\langle\lvert RM\rvert\rangle\sim30$. I agree with the previous authors[2] that there is a general rise in the mean absolute value of the Faraday rotation with increasing redshift. But a most important result now appears after redshifts of about $z=1.2$. The five quasars with redshifts $z\sim2$ definitely have $\langle\lvert RM\rvert\rangle\sim10$ rad/m^2 again. Kawabata *et al.* seem to explain this as arising from a disordered metagalactic magnetic field which dominates beyond a distance which corresponds to a redshift (cosmological) of about $z=1.4$. But on their picture, regardless of how disordered the field is outside $z=1.4$, the radiation must traverse the region between $z=1.4$ and the observer, and it should therefore be rotated by at least the ~30 rad/m^2 in that region. Although there are few data available they certainly indicate, using this model, that the $z\sim2$ quasars are closer than the $z\sim1$ quasars and are in fact at distances corresponding to the $z\sim0.1$ to 0.3 quasarlike objects.

This last result seems particularly significant because the evidence discussed earlier[5] indicated that the quasars with redshifts of the order of $z=0.2$ are low-luminosity Local Group objects, and that with higher redshifts the quasars become of higher luminosity and generally distributed throughout the local supercluster of galaxies. But for redshifts around $z\sim2$ the evidence indicated that they are once again low-luminosity objects distributed in space in the Local Group and nearby regions of the supercluster.

It is interesting to note from Table 1 that the Faraday rotations in the north galactic hemisphere are about evenly divided between plus and minus. We would conclude that this occurs as the radiation encounters concentrations of plasma in the local supercluster which have no preferred alignment. On the other hand, the ten Faraday rotations in the south

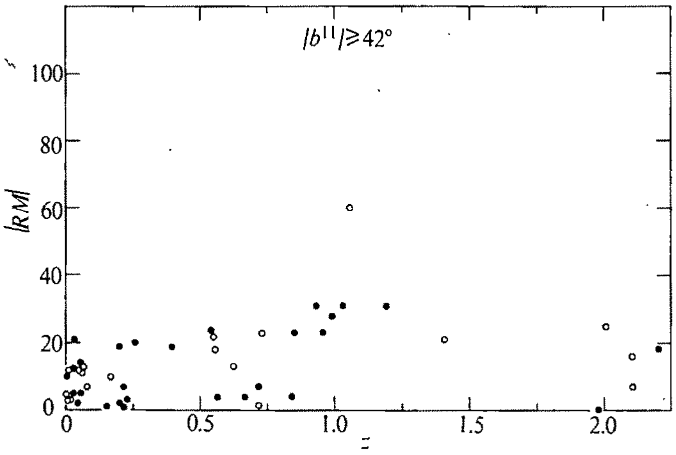

Fig. 2 Plot of Faraday rotation (●, positive; ○, negative) against redshift of source. Data from Reinhardt and Thiel, Table 1.

galactic hemisphere are almost all at least slightly positive. This may indicate there is some preferential alignment of magnetic field within our own Local Group of galaxies, the centre of which lies in the direction of M31 in the south galactic hemisphere. An additional point can be made about the quasars with very high redshifts. Of the seventeen quasars with redshifts greater than $z \doteq 1.5$ known in 1968, thirteen lie in the south galactic hemisphere. This would support the inference that they are Local Group objects concentrated in the general direction of M31.

Finally, it can be remarked that the previous authors[1-3] estimated a mean electron-density-magnetic-field component of $n_e B_{\parallel} \sim 10^{-14}$ along the path length to quasars if they were at their cosmological distances. If I use a distance on the average of 1/100 of this for the quasars, an $n_e B_{\parallel} \sim 10^{-12}$ would be derived for the local supercluster. Because we are dealing with the same order of extragalactic Faraday rotation as galactic, we can scale the observed galactic Faraday rotation near the plane in our own Galaxy (about 300 pc path length with $n_e B_{\parallel} \sim 10^{-7}$ to 10^{-8} gauss/cm^3) to the scale of the supercluster (about 30 Mpc). This yields $n_e B_{\parallel} \sim 10^{-12}$ to 10^{-13}, in agreement with the observations for the supercluster. This mean value of $n_e B_{\parallel}$ is reasonable, so the question arises of how might it be distributed along the line of sight. It must be between the two extremes of completely even, homogeneous spatial distribution and complete concentration into regions the size of the optical diameters of galaxies. If we indeed have some intermediate distribution of this Faraday rotating plasma—say on the scale of groups or clusters of galaxies—then we would expect the radio emission from quasars and compact galaxies to intersect regions of higher and lower $n_e B_{\parallel}$ as it crosses the supercluster, and suffer Faraday rotations of either plus or minus sense with an increasing dispersion as the distance across the supercluster increases.

Evidence for Black Holes in Binary Star Systems

ONE of the most exciting predictions of the general theory of relativity is that a star of more than about 1.4 $M_{\odot}$ may undergo gravitational collapse to produce a black hole when it has exhausted its nuclear fuel. It would therefore be a very important confirmation of the theory if such holes could be detected. Unfortunately their very small size (a few km) makes it virtually impossible to observe them directly, but their existence could be inferred from the motion of other objects in their gravitational field. The natural place to look for black holes therefore is in binary star systems in which only one object is observed (single line binaries). Thorne and Trimble[1] gave a list of all single line spectroscopic binaries in Batten's[2] catalogue in which the mass of the unseen object was estimated to be 1.4 $M_{\odot}$ or over. In most of these binaries the unseen secondary was less massive than the primary observed star and therefore could have been a normal star which is not observed in comparison with its brighter companion. In a smaller number of cases the secondary was heavier than the primary, but in each of these cases Trimble and Thorne were able to suggest a possible reason why it might not have been observed. They concluded therefore that while some of these single line binaries might contain black holes there was no compelling reason for believing that any of them did.

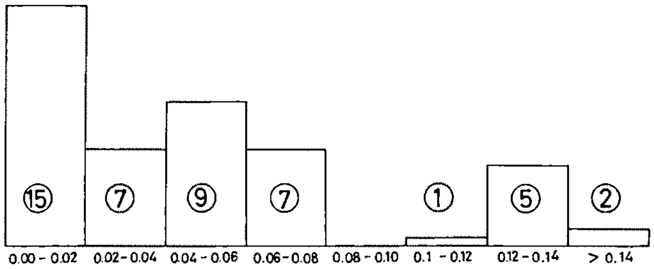

Fig. 1 The eccentricities of forty-six short period double line spectroscopic binary systems.

Here we would like to present an additional argument not considered by Trimble and Thorne. This suggests that at least one or two of these binaries may contain black holes. The evidence for this comes from studying the eccentricities of the shortest period binaries.

In a short period binary system (say, with a period of less than 5 days) one would expect any initial eccentricity of the orbits to be damped out. This is because of dissipation processes such as tidal friction, mass exchange and magnetic breaking which will reduce the energy of the system but not its angular momentum. The orbit therefore tends to that with the lowest energy for a given angular momentum, that is, a circular orbit. Suppose now that one of the stars collapses to form a black hole. Then in a time short compared with the orbital period it might lose a significant fraction of its mass by the emission of gravitational waves or the ejection of a shell of matter. In addition, in unpublished work by one of us (S. W. H.), it is shown that in the Brans–Dicke theory the object will lose the fraction of its mass which arises from the scalar interaction (~7%). This sudden mass loss will cause the orbit which was initially nearly circular to acquire an eccentricity of $e = \dfrac{\Delta M_2}{M_1 + M_2}$ where M_1 and M_2 are the final masses of the two stars and ΔM_2 is the mass loss of the second star. This eccentricity will eventually be damped away but at a rather slower rate because tidal dissipation will occur only in the star which has not collapsed. It will be observable if the collapse did not occur too long ago.

To test this idea we have compared the eccentricities of short period double line binaries—that is, binaries where both stars are observed—with those of short period single line binaries. We examined all the binaries in Batten's catalogue[2] with a period less than 5 days and where the masses of both objects were above 1.4 $M_{\odot}$ and where the quality of the data was not considered bad (class *a* to *d* in Batten's classification). In the case of the double line binaries we excluded those eleven where the eccentricity was assumed zero. In fact these probably have very low eccentricities. The distribution of eccentricities for double line binaries is shown in Fig. 1. From this it can be seen that most of them (38 out of 46) have very low eccentricities (below 0.08). There are eight binaries with eccentricities above 0.08. Seven of these have spectral types B3 or earlier and are probably younger than 10^8 yr. This indicates that the damping time for loss of eccentricity is probably of the order of 10^8 yr in a close binary. The eighth binary is exceptional in that its spectral type is AO which is considerably later and its eccentricity is 0.29 whereas the next highest eccentricity is 0.19. This spectroscopic binary is in fact one visual component of the visual double system γ Andromeda (ADS

1630). The other visual component of this system has a highly eccentric orbit which at periastron will pass fairly close to the spectroscopic binary. At each close passage it will be likely to change the eccentricity of the binary by a small amount. In 10^8 yr there will be more than a million such passages and so the present observed eccentricity could have been produced by a random walk process.

Table 1 shows all single spectroscopic binaries in Batten's catalogue which have periods less than 5 days and where Trimble and Thorne estimated that the masses of each object were greater than 1.4 $M_\odot$. They estimated the mass, M_1, of the primary from its spectral type and then obtained a lower limit on the mass M_2 of the secondary from the observationally determined quantity $f(M) = M_2 \sin^3 i/(M_1+M_2)^2$ where i is the angle between the line of sight and the normal to the plane of the orbit. Of the seven systems in this table one (HD 209961) has an eccentricity which was assumed to be zero. Of the remainder three (HD 176318, 201 G Sgr and HD 194495) have eccentricities greater than 0.08. On the basis of seven double line binaries out of forty-six with high eccentricities one would expect three or more out of a sample of seven with a probability of less than 8%. This is suggestive but it is not good enough for one to be confident that one or more of these binaries contains a black hole. But there is some supporting evidence for the black hole hypothesis in the fact that, whereas in the case of the double line binaries those with high eccentricities are among the earliest in spectral type, those single line binaries with high eccentricities are all distinctly later and are not among the earliest types in their class. We therefore suggest that it would be worth examining these three binary systems more carefully to see whether one could rule out the possibility that the secondary was a normal star which has not been observed to date because it is less luminous than the primary. In the case of 201 G Sgr the primary is a giant and so overluminous for its mass; one could therefore not hope to detect the secondary in this system; however, in HD 176318 and HD 194495 the secondaries, if they are normal stars, should be less than 3.4 and 2.7 magnitudes respectively down on the primaries. With the use of image intensifiers it might be possible to detect them. It might also be worth looking for these objects in other wave bands—Zel'dovich and Guseynov[5], for example, have pointed out that matter falling into a black hole could cause the emission of X-rays.

In 201 G Sgr and HD 176318 the lower limits on the mass of the secondary are just below the highest estimates of the maximum mass of neutron stars[6]. It is therefore just possible that these two could be neutron stars. In the case of HD 194495, however, the lower limit on the mass of the secondary is 2.8 $M_\odot$ which is too high to be a neutron star. If the present observed eccentricities of these systems resulted from mass loss,

$$\frac{\Delta M_2}{M_2 + \Delta M_2}$$

would be less than 0.39 for HD 176318, 0.21 for 201 G Sgr and 0.29 for HD 194495.

To summarize, there is suggestive but not conclusive evidence for the presence of black holes in binaries. The evidence could be strengthened by careful observations which could rule out the possibility that the secondaries in these binaries are normal stars.

We thank Dr Virginia Trimble for help and advice.

Arctic Palaeotemperatures in Late Caenozoic Time

RECONSTRUCTION of the climatic and hydrologic history of ocean basins has been based on either oxygen isotope palaeothermometry or studies of foraminiferal assemblages preserved in deep sea sediments. We report here the application of both methods to deep sea sediments collected from the Arctic Ocean by the Lamont–Doherty Geological Observatory. Oxygen isotope determinations were made on two selected cores from the central Arctic basin to test the validity of the palaeoceanographic interpretations based on microfaunal analysis[1–3]. Details of the cores are given in Fig. 1 and Table 1. Analyses of the cores have already been published in detail: here we wish to summarize what we have discovered about the history of the Arctic Ocean[1–4].

Biostratigraphic and lithologic correlations between cores accompanied by $^{18}O/^{16}O$ determinations and radiometric

dating were used to estimate ages and sedimentation rates as well as to reconstruct the climatic and oceanographic history of the Arctic[3,4]. The time interval of the longest core (T3-67-12, Fig. 3) is thought to exceed 3.3. m.y. Ages were estimated by interpolations and extrapolations based on radioisotope determinations[5] and close interval faunal and lithologic correlations with neighbouring cores that have an established palaeomagnetic stratigraphy. Age assessments have been modified from those presented in a previous publication[3], due to reinterpretation of the palaeomagnetic data of core 224 by Clark and his colleagues[6]. The earlier palaeomagnetic ages[7,8] had apparently been greatly over-estimated.

On the basis of faunal and sediment characteristics three climatic units can be distinguished. The oldest, unit III, was deposited between about 3.3 m.y. and 3 m.y. ago; it consists of foraminifera-poor, Fe and Mn oxide-rich sediments. Calcareous foraminifera, in part corroded, are thick shelled forms. Arenaceous foraminifera (*Glomospira gordialis*, *Cyclammina pusilla* and *Alveolophragmium subglobosum*) dominate the benthic assemblages. Lower than present sedimentation rates could account for the selective solution of the less resistant limy tests and impoverished character of the fauna.

Unit II was deposited between approximately 3 and 0.7 m.y. ago and is poor in both Fe, Mn oxides and in foraminifera. It contains one foraminifera-rich layer: the predominant foraminifer in this layer is temperate–arctic, euryhaline *Globigerina quinqueloba* ($^{18}O/^{16}O$ determinations). This species occurs with sinistral *Globigerina pachyderma* throughout unit II. Fragile calcareous benthonic foraminifera (*Stetsonia horvathi*, *Sphaerodina bulloides* and *Bolivina arctica*) periodically abound, constituting up to 88% of the fauna. Concentration of thin walled benthonic foraminifera suggests that the near absence of planktonic forms was due to adverse environmental conditions rather than to dissolution of the less resistant tests. It has been suggested that the Arctic was essentially free of permanent pack ice during the deposition of units II and III (refs. 2, 3).

Unit I was deposited in the past 0.7 m.y., a time of conspicuous climatic fluctuations as indicated by the temporal variations in fauna and in mineral/fauna ratio (Fig. 2 and Fig. 3). Beds rich in both foraminifera and in Mn, Fe oxides alternate with layers poor in both foraminifera and Mn, Fe oxides. The former represent conditions similar to present (permanent pack ice cover) and contain sinistral *G. pachyderma* almost exclusively[3,4]. *G. quinqueloba* attained high frequencies at the beginning and end of some of these cold periods. In the foraminifera-poor beds, sinistral *G. pachyderma* is accompanied by *G. quinqueloba*. Pteropods (*Limacina helicina*) are preserved principally in core tops. Unit II/unit I boundary approximately corresponds to the last major polarity reversal in the Earth's magnetic field conveniently marking the Brunhes/Matuyama boundary[3]. Ice rafted débris throughout the cores indicates that high latitude glaciation commenced before 3.3 m.y. ago.

Among the factors determining surface water salinity in the Arctic, precipitation, evaporation, ocean currents, convective mixing and the presence of drift ice are considered most important and the oxygen isotopic composition of Arctic surface water is determined by the same factors[9]. Evaporation results in concentration of ^{18}O while precipitation and river inflow cause its dilution. The range of present day surface water temperature and salinity is $-1.6°$ C to 0° C and $<29^{0}/_{00}$–$33^{0}/_{00}$ respectively[10].

As a result of slow vertical mixing, present day surface salinities are about $4.8^{0}/_{00}$ lower than those of the bottom water[10]. Analysis of $^{18}O/^{16}O$ for Arctic water[11] indicates that the ^{18}O

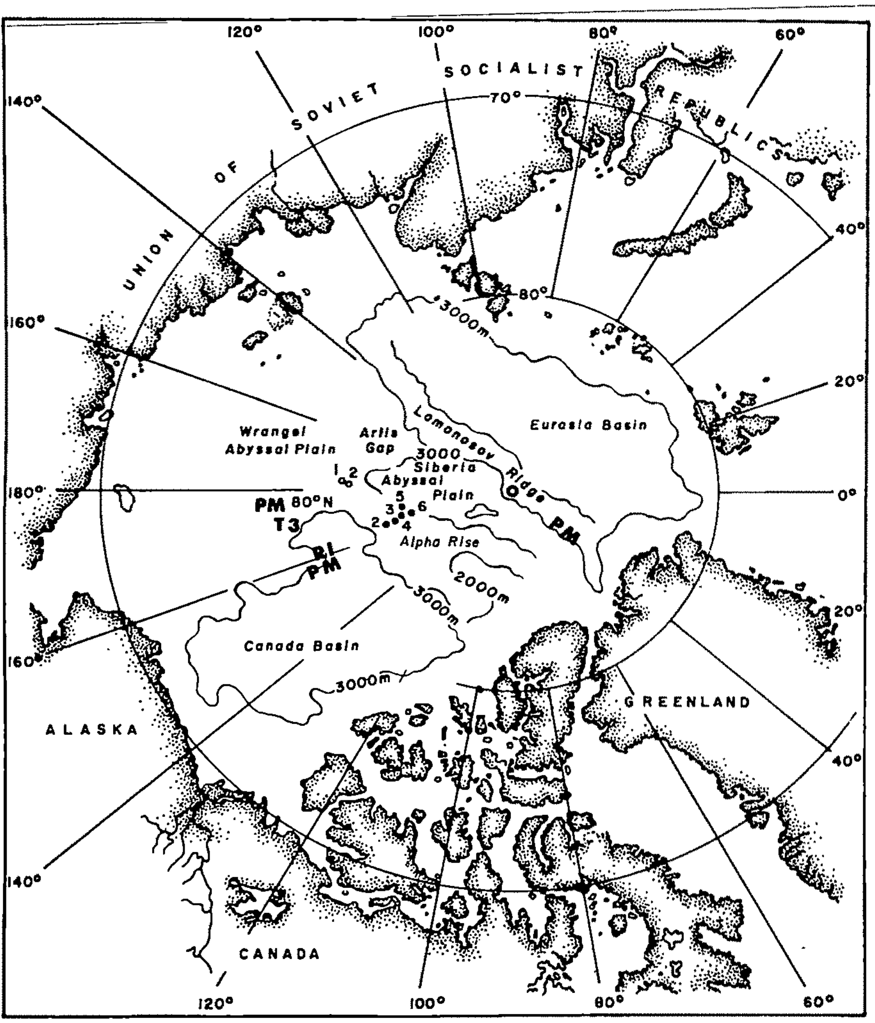

Fig. 1 Bathymetric map of the Arctic Ocean based on the geological map of the Arctic (1960). T3 shows the location of cores T3-67-4,9,11,12 while PM shows the location of cores with known palaeomagnetic stratigraphy and RI locates the radioisotopically dated core. Dark and light circles show location of previously studied cores[1-3].

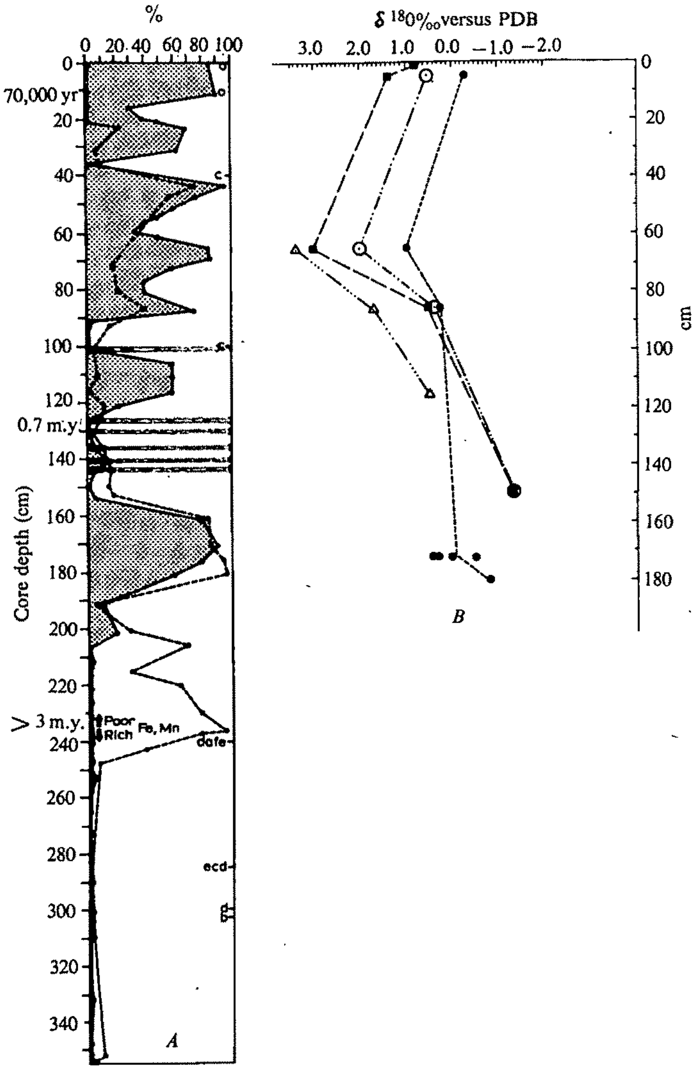

Fig. 2 Core T3-67-9. *A*, Variation of microfauna to clastics in the coarse fraction (>62 μm). The shaded areas represent volume percentages of microfauna. The occurrence of low latitude foraminifers is as follows: *a*, *Globorotalia menardii—tumida*; *b*, *Globorotalia scitula*; *c*, *Globorotalia* sp.; *d*, *Globigerinoides* sp.; *e*, *Globigerinoides ruber*; and *f*, *Sphaeroidinella dehiscens*. The circles represent pteropods and the dashed line gives the percentage of *G. quinqueloba* complex out of the total planktonic population. Dark horizontal lines are horizons where benthonic foraminifers are in excess of 10%. *B*, The variation in $\delta^{18}O$ for: ■, *G. pachyderma*; ●, *G. quinqueloba*; ○, average planktonic species; and △, total planktonic and benthonic foraminifers.

depletion closely follows the salinity profile, with $\delta^{18}O$ changing by 0.8‰ with 1‰ change in salinity in the upper 350 m. This surface seawater is depleted in ^{18}O by about 4‰, while at greater depth $\delta^{18}O$ approaches values close to SMOW.

The $^{18}O/^{16}O$ ratios of calcareous tests from foraminifera-rich and foraminifera-poor layers were determined (Figs. 2 and 3). The measurements were made on an Atlas-Werke M86 mass spectrometer developed by Nier. The foraminifers were hand picked, and treated with commercial 'Clorox' solution; the CO_2 was extracted from the $CaCO_3$ according to the method described by McCrea[12].

To calculate the temperatures from the $^{18}O/^{16}O$, the formula of Epstein *et al.*[13], modified by Craig[14], was used

$$t = 16.9 - 4.2\,(\delta s - \delta w) + 0.13\,(\delta s - \delta w)^2$$

The established relation

$$\left(\delta s\ ^{18}O = \frac{^{18}O/^{16}O \text{ sample}}{^{18}O/^{16}O \text{ standard}} - 1 \times 1{,}000\right)$$

depends on the water temperature (t° C) as well as on the isotopic composition of the water in which the organisms lived.

When sufficient shell material was available, planktonic tests were analysed separately from the benthonic forms. Moreover, when samples yielded adequate amounts of the two dominant planktonic foraminifers, *G. quinqueloba* and *G. pachyderma*, their tests were analysed separately. As indicated in Figs. 2 and 3 the former registered consistently lower $\delta^{18}O$ values than the latter. This can readily be explained by their differing life habitats: *G. quinqueloba*, an epiplanktonic form, incorporates the $CaCO_3$ necessary for test building at surface, in the isotopically lighter, low salinity water, whereas the thick shelled *G. pachyderma*, known to inhabit greater water depth[15], constructs the early part of its shell at surface, and the outer, thick cortex at greater depth, in denser, more saline water, hence its great $^{18}O/^{16}O$ value. Determinations of $\delta^{18}O$ made on composite samples of benthonic and planktonic foraminifers indicate that, with one exception, the bottom water was enriched in ^{18}O (Figs. 2 and 3) attesting to the restricted vertical mixing and subsequent density stratification of the Arctic water.

As mentioned previously, changes in the $\delta^{18}O$ of the seawater are reflected in the oxygen isotopic ratios of the calcareous foraminiferal tests. The greatest shift towards positive values occurs at 65 cm depth in core T3-67-9 and at 40 cm depth in core T3-67-12 (Figs. 2 and 3); both samples come from foraminifera-rich horizons and were deposited during a period when seawater was colder and/or more saline than today.

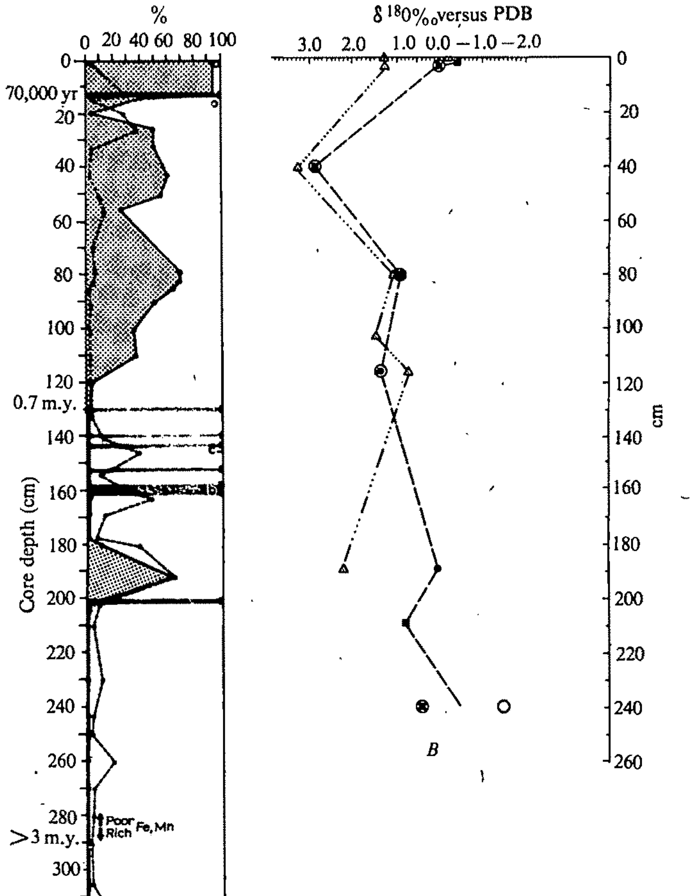

Fig. 3 Core T3-67-12. *A*, Variation in microfauna to clastics. Same legend as for Fig. 2. *B*, Variation in $\delta^{18}O$. Same legend as for Fig. 2.

Below 85 cm $\delta^{18}O$ values are more negative than in the core "tops" suggesting slightly warmer and/or less saline water in the Arctic basin between 3.3 and 0.7 m.y. ago than those of the present.

In conclusion, oxygen isotope and palaeontological determinations of planktonic foraminifers allow us to make several generalizations on the palaeoceanographic history of the Arctic Ocean back to Mid Pliocene. We conclude that the surface and deep water underwent periodic fluctuations and that the average surface water temperatures have varied between about $-2°$ C and $+0.5°$ C, with salinities ranging from approximately $36^0/_{00}$ to $<29^0/_{00}$, during the time interval represented by the cores investigated. This assumption is based on the $^{18}O/^{16}O$ data combined with the estimated environmental requirements of the extant planktonic foraminiferal species[15].

Temperature minima correspond to the upper Pleistocene, probably the Riss (Illinoian) or Würm (Wisconsin) Glacial, whereas higher temperatures and/or lowest salinities were registered by foraminifers between about 3.3 million and 0.7 million years BP.

We thank P. E. Rosenberg and J. R. O'Neil for valuable suggestions, K. Hunkins for collecting the cores and R. Capo for shipping the samples. Coring operation was supported by ONR and NSF grants to Lamont-Doherty Geological Observatory.

Palaeoclimatic Significance of the Stagnation of the Cariaco Trench

ALMOST all available information about the past thermal behaviour of the oceans has been obtained by studying the oxygen isotope ratios of cores from the deep sea[1]. One basic limitation of that method is that to derive a palaeotemperature curve from oxygen isotope data one must assume some initial value for the oxygen isotope ratio in the ocean at the time each sample was formed. There has been little independent evidence of past oceanic temperatures to provide a check on these assumed values, and some questions have been raised[2] about the significance of the $^{16}O/^{18}O$ palaeotemperature record. I suggest that the deep water of the Cariaco Trench may provide an estimate of the late glacial surface temperature of the Caribbean Sea which is completely independent of the oxygen isotope method.

The Cariaco Trench is a small closed basin off the coast of Venezuela with a sill depth of about 146 m and a maximum depth of 1,400 m[3,4]. The water in the trench is presently anaerobic below a depth of 375 m and isothermal below 250 m, but sediment cores indicate that during late glacial time the bottom of the trench was ventilated and that the present stagnant condition developed about 10,900 radiocarbon years ago[4,5–7].

I suggest that during the late glacial period of ventilation of the deep waters of the Cariaco Trench, oceanic cooling and overturning enabled oxygenated surface waters to descend to the bottom of the trench; the isothermal and isohaline conditions must then have extended to the surface, because of vigorous mixing. These conditions ended when surficial warming at the beginning of the postglacial established a stable stratification; the deep water of the trench has been isolated since that time. I therefore regard the deep water as "fossil" late glacial age surface water in some respects. In particular, the deep water can hardly have cooled since the late glacial, because the overlying water is warmer than the deep water, and the geothermal heat flux prevents loss of heat downwards. Therefore, I regard the present deep water temperature of 16.9° C as the maximum possible surface temperature for the waters of the Cariaco Trench at the end of the last glaciation. This is in contrast to the modern values of 24° C to 26° C (ref. 3), and implies a temperature difference of at least 7° C between the late glacial period and the present.

This interpretation provides an unusual opportunity to check some of the assumptions which must be made in oxygen isotope work.

Monolithic Light Emitting Diode Arrays using Gallium Phosphide

THE high diode packing densities that can be achieved on single crystal slices of semiconductors mean that monolithic arrays of light emitters offer the possibility of displaying typescript signed characters from a 7 × 5 matrix, either for direct visual applications or for data recording. Previously this has only been achieved using the direct band gap semiconductors gallium arsenide and gallium arsenide phosphide, which emit radiation in the infrared or extreme red parts of the spectrum. Two problems have prevented gallium phosphide being used in monolithic arrays; they are the low electroluminescent efficiencies obtained from junctions formed by diffusion into indirect band gap materials and the lack of an adequate mask for use on gallium phosphide to define the diode areas during gaseous zinc diffusion.

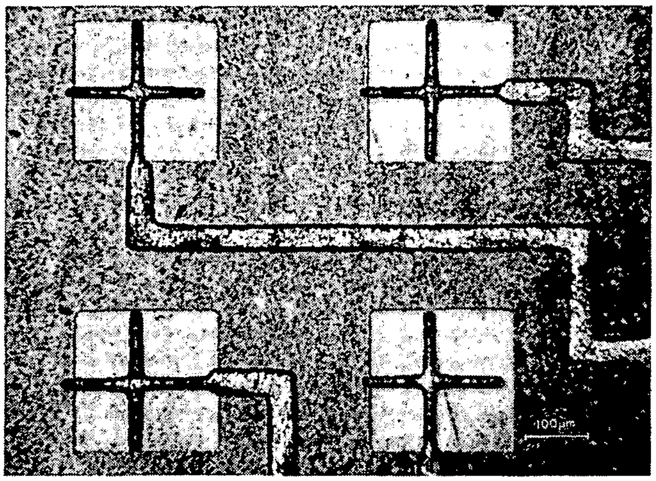

Fig. 1 Photograph of four diodes in a monolithic array. The diode squares are light emitting zinc diffused areas, the remainder of the surface being covered by the dielectric mask. Contact is made to the devices by aluminium interconnectors, the cross structure being used on top of the diode to facilitate current spreading.

We have fabricated green emitting monolithic arrays from epitaxial layers of gallium phosphide grown from gallium solution onto substrates cut from ingots produced by the liquid encapsulated Czochralski process[1] or grown by the vapour transport method[2]. These layers were doped with sulphur so as to have a carrier concentration in the range 5×10^{16}–10^{17} cm^{-3} and had nitrogen added so as to give a concentration in the semiconductor of approximately 2×10^{18} atoms cm^{-3}. The nitrogen substitutes for the phosphorous atom in the lattice, so acting as a shallow trap which is responsible for the green emission process[3]. In order to produce a p–n junction we have then diffused zinc into the layer at 650° C resulting in a surface zinc concentration of 3×10^{18} atoms cm^{-3}. The relatively low zinc level produced in the material enables the conditions for good electroluminescent efficiencies in an indirect band gap material to be established. The diode areas have been defined by diffusing through holes cut by photolithographic techniques in a triple mask of silica, silicon nitride and silica. This structure has excellent adhesion to the gallium phosphide and also has a low porosity to zinc atoms, so enabling it to act as an effective diffusion mask.

The monolithic arrays produced by this process have had electroluminescent efficiencies for green emission up to 0.1% at a current density of 20 A cm^{-2}. This compares with the best reported figure of 0.35% for individual diodes produced by the more complex double liquid epitaxial process grown on Czochralski substrates[4].

This work was carried out in part under a CVD contract and is published by permission of the UK Ministry of Defence (Navy Department).

Drag Reduction arising from Adhesive Tapes

Cossar has reported[1] that the presence of a uniform layer of double-sided adhesive tape ('Scotch' brand) on the floor of a water channel can have a significant influence on the mean-velocity profile in the boundary layer of a turbulent flow. Indeed, Cossar's experiments indicate that, in his operating conditions, the velocity distribution above a layer of adhesive tape is almost the same as that obtained in flow over rough boundaries for which the mean height of roughness is about 0.040 inches (0.116 cm). He accordingly suggested that 'Scotch' tape is physically "sticky" towards water. But Cossar's interpretation of his results is open to question: it may be that, rather than increasing the resistance to the flow, the influence of the adhesive tape reduces it. This conclusion can in fact be inferred from Cossar's results. For flows past smooth boundaries, the shear stress τ exerted on the boundary is related to the viscosity η and the normal velocity gradient by

$$\tau = \eta\left(\frac{\partial u}{\partial y}\right)_{\text{wall}} \tag{1}$$

where u is the tangential velocity and y is the normal coordinate. But this is a good approximation only for boundaries that are hydraulically smooth, in the sense that the surface irregularities lie within the viscous sublayer of the flow. If, on the other hand, the roughness elements at the boundary are large enough, they can contribute to the shear stress exerted on the boundary through an effective form drag (see ref. 2, page 376), and then equation (1) is invalid. Indeed, it is usual for values of $\partial u/\partial y$ near the wall to decrease as the surface roughness increases (compare Cossar's results), although the actual shear stress exerted on the boundary increases. If we now make the assumption that the adhesive tape in Cossar's experiments was hydraulically smooth, it follows that the observed reduction in $\partial u/\partial y$—which presumably extends right up to the wall—is accompanied by a reduction in shear stress, compared with what it would be on a smooth insoluble wall.

If these conclusions are correct they might have some interesting implications, for it would seem that the drastic changes in flow properties observed by Cossar emanate from the absorption into solution of some adhesive from the tape. But the solubility in water of the gum of such adhesive tapes is rather low, which suggests that only extremely small quantities of additive are needed to change the structure of the turbulent boundary layer, provided the additive is supplied in "sensitive" areas.

Naturally these ideas are speculative. To check them some solutions of adhesive were made by soaking pieces of tape in water, and then the drag reduction properties of these solutions were measured in turbulent pipe flows.

The apparatus used consisted of a hypodermic syringe to which a 93 cm length of hypodermic tubing of 1 mm bore was attached. The syringe was filled with the solution to be tested, and a known pressure was applied to the plunger of the syringe, forcing the liquid through the small-bore tubing. An electronic counter was used to measure the time for a given quantity of liquid (usually 10 ml.) to be ejected. The ejection times determined in this way were easily reproducible, for a given fluid, to within ±2%. The drag reduction was taken

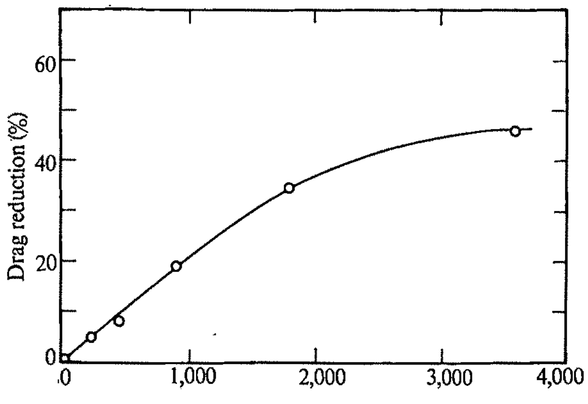

Fig. 1 Drag reduction of a solution of 'Scotch' tape in petroleum ether. Solvent Reynolds number was 60,000.

to be the fractional increase in the flow rate of the sample over that obtained for the solvent alone.

In view of Cossar's results it was initially anticipated that an extremely dilute solution, obtained from soaking 'Scotch' tape in water, would give rise to a large drag reduction. But early attempts to observe the Toms effect with such solutions proved unfruitful, and it was only after prolonged soaking of the tape that any effect was observed. For example, after soaking 0.02 m^2 of 'Scotch' tape in 200 ml. of water for 40 days, the resulting solution showed a drag reduction of 19% compared with water when ejected at a Reynolds number of 8,200. With another proprietary brand of adhesive tape ('Sellotape') the same procedure gave a drag reduction of 8% which rose to 20% after 80 days of immersion. In connexion with these measurements it is perhaps worth noting that: (i) the viscosity of the 'Scotch'-tape solution, measured under laminar flow conditions, was about 6% greater than that of water at the same temperature; and (ii) the drag reduction remained unchanged when the adhesive tape solutions were passed through filter paper (Whatman No. 1 grade) before being tested.

To obtain a solution of known concentration, the gum from a sample of 'Scotch' tape was completely dissolved in a "good" solvent (petroleum ether). The properties of this solution are not expected to differ greatly from those of the corresponding aqueous solution. The values of the drag reduction obtained at various dilutions are shown in Fig. 1. At a concentration of 3,600 p.p.m.w., when the viscosity of the solution was 50% greater than that of the solvent, the drag reduction was 46%. The results in Fig. 1 suggest that, compared with some drag reducing compounds, the concentrations of the present solutions need to be quite large in order to produce substantial drag reduction. On the other hand, if our suggestions regarding Cossar's experiments are correct, it would seem from his results that only extremely small quantities of additive can have large influences on a turbulent boundary layer when it is supplied from the wall. Accordingly it might be highly effective, for drag reduction, to coat surfaces with such compounds, which, because of their poor solubility in water, could have a fairly long period of effectiveness.

BIOLOGICAL SCIENCES

Quantitative Evidence for Protein Denaturation as the Cause of Thermal Death

THE specific cause of the death rates of unicellular organisms and poikilothermic animals at high temperatures is not known for certain[1]. We wish to report a good numerical correlation between certain thermodynamic parameters in protein denaturation and death rates, where these have been reported, for these organisms. A similar correlation may exist between the thermal denaturation of other biopolymers, such as DNA and RNA, and thermal death, but in the absence of adequate data we cannot consider this possibility further.

At sufficiently high temperatures (>315 K) most proteins denature with pseudo-first order kinetics. This implies that the renaturation rate is slow enough to be negligible, and the rate is described by $\mathrm{d}n/\mathrm{d}t = -k_D n$. The first order denaturation rate constant, k_D, varies exponentially with temperature and is usually described by the absolute rate theory equation[2]

$$k_D = \kappa \frac{k_B T}{h} \exp[\Delta S^\ddagger/R] \times \exp[-\Delta H^\ddagger/RT] \qquad (1)$$

where $\Delta S^\ddagger$ and $\Delta H^\ddagger$ are the activation entropy and activation enthalpy respectively.

We have found evidence from the work of Williams and Milby[3] on the thermal denaturation of rhodopsins that, for the proteins tested, the $\Delta S^\ddagger$ and $\Delta H^\ddagger$ values were related by the simple linear equation[4]

$$\Delta S^\ddagger = a\Delta H^\ddagger + b \qquad (2)$$

The existence of such a relationship constitutes a compensation law behaviour, because variations of $\Delta H^\ddagger$ in the negative exponential of equation (1) are partially compensated by parallel variations of $\Delta S^\ddagger$ in the positive exponential in their effects on k_D. (At the temperature $T = 1/a$, the compensation is exact and the denaturation rate is independent of the values of $\Delta H^\ddagger$ and $\Delta S^\ddagger$. This temperature, T_c, is the compensation law temperature.) Such compensation law behaviour occurs in a number of physical and chemical processes[5-9] for which *ad hoc* explanations have been suggested. So far there is no compelling evidence that such a rule as equation (2) can be derived from general thermodynamic principles. Exner[10] has pointed out that, in certain limited conditions, a compensation law may occur accidentally, and he has provided a set of criteria for judging the reliability of the rule. In some of the cases described here, such criteria have been used and satisfied.

We tested the generality of such a compensation law using the compilation of thermodynamic data on protein denaturations from Joly[11]. Fig. 1 presents all these data, plotted as $\Delta S^\ddagger$ versus $\Delta H^\ddagger$, with no selection. All the data cluster about a linear regression line. From a least squares fit of the data points, the line yields a value of $T_c (= 1/a)$ of 329 K and a value of $b = -64.9$ calories/mol × K (an equally valid intercept could be the value of $\Delta H^\ddagger$ when $\Delta S^\ddagger = 0$; this yields $\Delta H^\ddagger = 21.3$ kcalories/mol). The corresponding values for the rhodopsins are: $T_c = 334$ K and $b = -66$ calories/mol × K. Several of the proteins are represented by a number of points, each referring to a specific *p*H or ionic strength of the solution. Therefore, although the $\Delta S^\ddagger$ and $\Delta H^\ddagger$ values for a given protein may vary depending on the experimental conditions, the values always fall on the same line.

Sukhorukov and Likhtenshtein[12] have published a plot similar to Fig. 1 for a large number of proteins, which overlap only partially the proteins of our figure. The values we have estimated from their plot are: $T_c \simeq 325$ K, $b \simeq -70$ calories/mol × K, which are closely similar to ours. They have also included proteins and viruses in the dry state, as well as proteins in alcohol–water mixtures, and in D_2O solution, all of which still fall on the compensation law line.

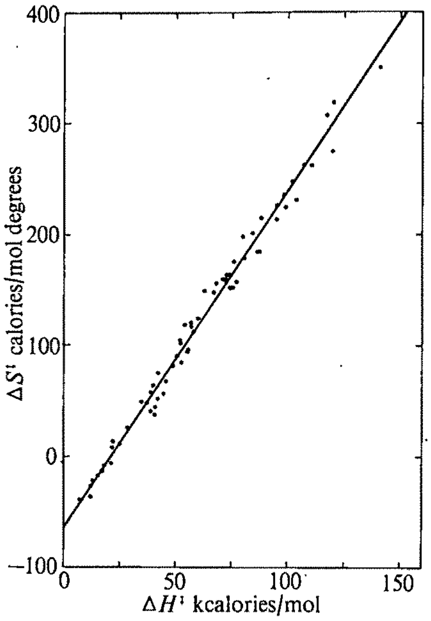

Fig. 1 A plot of the activation entropy, $\Delta S^\ddagger$, versus the activation enthalpy, $\Delta H^\ddagger$, for protein denaturation (after Joly[11]). The regression line is a least squares fit to the data, and the close clustering to the line indicates the validity of the compensation law (equation 2). The constants of the line are: $T_c=329$ K, and $b=-64.9$ calories/mol × K.

We conclude that virtually all proteins[7], in a variety of conditions, denature at elevated temperatures according to the compensation law of equation (2), with the same value of T_c and b.

Lumry (personal communication) has called our attention to the work of van Uden and his co-workers[13] who have reported compensation law behaviour in the thermal killing of yeasts. Here again (1) the death rates followed pseudo-first order kinetics with respect to time; (2) the specific thermal death rate, k_D, depended exponentially on temperature; and (3) the $\Delta S^\ddagger$ and $\Delta H^\ddagger$ values obtained were correlated according to equation (2). From their data we have calculated the values of the compensation law constants as $T_c=325$ K and $b=-64.5$ calories/mol × K.

We have attempted to pursue this correlation with other unicellular organisms such as viruses and bacteria. Usable data in the literature are surprisingly scant, but Barnes *et al.*[14] have carefully investigated this compensation law in the thermal inactivation of the Sindbis virus. Their data again meet the three criteria described above, and they calculate $T_c=330$ K; while we calculate $b=-64$ calories/mol × K. In the case of bacteria, data are available on *Pseudomonas fragi*[15], *Staphylococcus aureus*[16,17], and two strains of *Salmonella*[17] which also meet our three criteria. The values we have calculated for the compensation law constants are $T_c=331$ K and $b=-65$ calories/mol × K.

We have plotted all the points for the yeasts, virus and bacteria in Fig. 2. In Table 1 we collect all the values of the constants for comparison. The unicellular organisms have a specific death rate for thermal killing which follows a compensation law with constants which are in very good agreement with the constants for thermal denaturation of proteins. We suggest that this is good quantitative support for the general hypothesis that protein denaturation is the cause of thermal death in unicellular organisms. Such a statement, however, does not allow the identification of any specific protein as the limiting cause, because the cells will have different $\Delta S^\ddagger$, $\Delta H^\ddagger$ values in different environmental conditions, and any specific protein will exhibit a class of $\Delta S^\ddagger$, $\Delta H^\ddagger$ values in different environmental conditions *in vitro*. It may be possible, though difficult, to find an isolatable protein, or group of proteins, the $\Delta S^\ddagger$, $\Delta H^\ddagger$ values of which *in vitro* coincide with those of the cell for the same conditions, and draw the inference that this (these) is (are) the limiting protein(s). The viruses, constituted with a small number of proteins, recommend themselves for such a study.

Table 1 Comparison of Compensation Law Constants, T_c and b, from : $\Delta S^\ddagger = a\, \Delta H^\ddagger + b$; $T_c = 1/a$

	T_c (K)	b (calories/mol × K)
Proteins	329	−64.9
Virus	330	−64
Yeasts	325	−64.5
Bacteria	331	−65

In a cell, a protein i is manufactured with a creation rate c_i, and has a denaturation rate, $k_{D_i} n_i$ (again we ignore renaturation, although it could be subsumed under c_i); therefore we have:

$$\frac{dn_i}{dt} = c_i - k_{D_i} n_i \qquad (3)$$

If a steady state could occur, then the number of molecules of protein i is $n_i = c_i/k_{D_i}$. The creation rate c_i must be assumed to be a complex function of both the genetic structure and environmental conditions. For a population of cells to die with pseudo-first order kinetics, the temperature must be high enough that the denaturation rate overwhelms the ability of the cell to create the proteins that are limiting, and $dn_i/dt = k_{D_i} n_i$. If N is the number of viable cells, then our hypothesis requires that $dN/dt = -k_{D_i} N$. It is not obvious why the k_{D_i} for the cell population should be identical with k_{D_i} for the protein population. For example, the assumption that a threshold number of proteins, i, is essential for cell viability would lead to a single time instant of death for all the cells of the population, rather than a constant probability of death as the kinetics require. It can be shown mathematically that at least three hypotheses connecting protein denaturation with cell death could lead to the appropriate kinetics and thermodynamics. These are (*a*) that there is a statistical distribution of protein concentration thresholds in the population of cells; (*b*) that the stress on the cell to create protein at a rate sufficient to compensate the denaturation rate is the cause of death; and (*c*) that the stress on the cell to prevent the accumulation of denatured protein

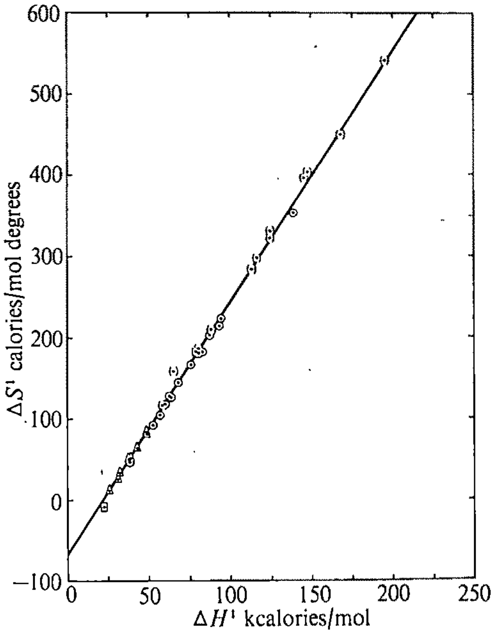

Fig. 2 A plot of the activation entropy, $\Delta S^\ddagger$, versus the activation enthalpy, $\Delta H^\ddagger$, for thermal killing of various organisms: (·), yeasts (after van Uden *et al.*[13]; ⊙, bacteria (after Luedecke[15], Walker[16], and Beamer and Tanner[17]); △, virus (after Barnes *et al.*[14]); and ⊡, *Drosophila m.* (after Strehler[18]). The constants of the line are: $T_c=325$ K and $b=-66$ calories/mol × K.

debris kills the cell. There are undoubtedly other possible hypotheses which should be tested.

In Fig. 2 we have plotted a single point on the line which refers to the multicellular poikilotherm, *Drosophila melanogaster*, after the data of Strehler[18]. We have replotted his death rate curves to obtain the first order kinetic plots versus time. These k_Ds do show an exponential dependence on the temperature; and using equation (1), we have calculated the $\Delta S^\ddagger$ for these data. The datum point falls on the line close to the $\Delta S^\ddagger \simeq 0$ value. Strehler[1] has pointed out that a number of other studies on arthropods (*Drosophila*, *Pinus tectus* and *Daphnia*) have shown almost identical activation energies for the rate of ageing (as measured by the mortality rate) and these would yield data points close to $\Delta S^\ddagger \approx 0$, according to our estimates. We can now speculate that, if this is so, it has at least two explanations. First, the evolutionary jump from unicellular to multicellular organisms can be represented on the compensation law plot as the convergence of the $\Delta H^\ddagger$ values to the lowest value consonant with $\Delta S^\ddagger \geq 0$. That means that the arthropods have accepted a higher thermal death rate still consistent with survival of the species, for a smaller variation of the thermal denaturation rate of the limiting proteins with ambient temperature changes. Second, Sukhorukov and Likhtenshtein[12] have shown that many dry proteins fall on the compensation law plot at $\Delta S^\ddagger \approx 0$, and that hydration of these proteins causes the $\Delta S^\ddagger$, $\Delta H^\ddagger$ values to move up the line. $\Delta S^\ddagger \approx 0$ may be the smallest value that can be reasonably expected in biological circumstances; therefore one could argue that in going up the evolutionary scale, "dry" proteins are first encountered in vital roles at the level of multicellular organisms. Because these proteins denature fastest, they represent the rate limiting step in the death of these organisms. These latter arguments are purely speculative.

This work was supported in part by contracts from the Office of Naval Research and the Atomic Energy Commission.

Note added in proof. A fourth hypothesis connecting protein denaturation and cell death was proposed by Rahn in 1929 (Rahn, O., *Bact Rev.*, **8**, 1; 1944). According to him, "a logarithmic order is possible only when death is due to the destruction of a single protein molecule in the cell". We find this the most attractive alternative, with some interesting ramifications which we will develop later.

Preparation and Characterization of an Arylsulphatase insolubilized on Porous Glass

THE enzyme sterol sulphate sulphohydrolase (EC 3162) is used for the hydrolysis of steroid conjugates before analysis of body fluids for total oestrogens; but it is rather costly. The availability of a re-usable derivative of this enzyme which would be stable for a long time might be of value to the clinical chemist. I therefore decided to prepare an insolubilized derivative of this enzyme and determine its properties.

The enzyme was purchased as a mixture of β-glucuronidase/arylsulphatase (Boehringer). The arylsulphatase activity of the commercial preparation was 2.6 IU/ml. of enzyme solution. The insoluble enzyme was prepared as previously described[1-3]. Porous glass used for this study was 96% silica particles, pore diameter 550 Å, 40/60 mesh particle size. The enzyme was coupled through azo linkage to the glass. The insoluble enzyme was assayed with 0.001 M *p*-nitrophenylsulphate dissolved in 0.25 M Na_2CO_3 buffer (*p*H 9.0). The assay was carried out using 25 ml. of substrate to which was added a known weight of enzyme derivative. The reaction was continued for 10 min after which a sample was taken and read spectrophotometrically at 410 nm. The reaction was carried out at 25° C. Activity of the final product was 0.31 IU/g of glass. All other studies were carried out by the column method.

One gram of derivative was packed into a small, glass, 1.0 cm wide, jacketed column to a height of 5.0 cm. Temperature was maintained at 6° C throughout these studies.

A *p*H profile was obtained by passing 1×10^{-5} M *p*-nitrophenylsulphate through the column at a flow rate of 0.67 ml./min. The column effluent was continuously monitored at 410 nm in a flowthrough colorimeter. The buffers used were 0.25 M acetate between *p*H 5.0 and 6.7 and carbonate between *p*H 7.8 and 10.5. The *p*H optimum lies between *p*H 9.0 and 9.5 (Fig. 1).

By passing substrate at increasing concentrations through the column while maintaining constant flow rate (0.67 ml./min), the values for K_m and V_{max} were obtained (Fig. 2). The apparent V_{max} for the insoluble enzyme was 1.67×10^{-8} mol/s. The apparent K_m was 1.57×10^{-3} M. These values were

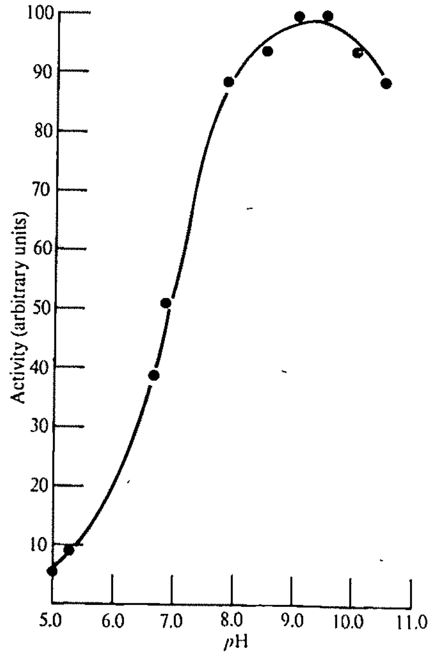

Fig. 1 *p*H profile using 1×10^{-5} M *p*-nitrophenylsulphate as substrate.

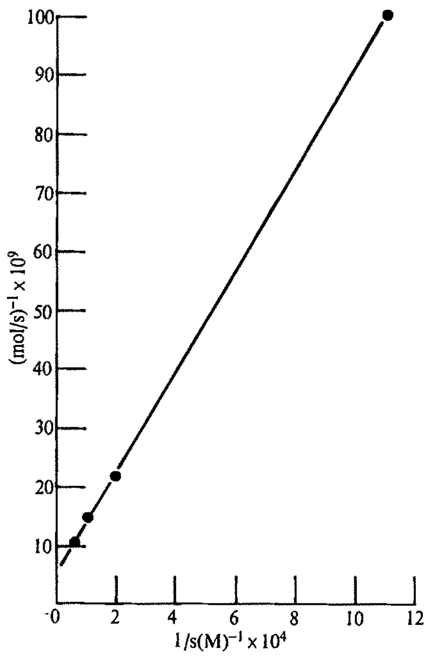

Fig. 2 Plot of 1/v against 1/(S). Substrate was *p*-nitrophenylsulphate in 0.25 M $NaCO_3$ (*p*H 9.0).

within 20% of values we obtained experimentally for the soluble enzyme at the same enzyme concentration.

The hydrolytic rate using 2.5×10^{-4} M substrate was found, as expected, to be inversely related to flow rate (Fig. 3). The relationship is not inversely proportional, however, and the curve seems very quickly to become asymptotic. Although the difference in flow rate between 0.67 ml./min and 3.0 ml./min is approximately 4.5 ×, the product concentration is decreased only 70%. The actual enzyme velocity of the insoluble derivative thus seems to increase with increasing flow rate, causing the asymptotic curvature. The apparent increased velocity is probably caused by the increased turbulent flow which decreases the film layer resistance at the surface of the particles. Because the substrate concentration used for the experiment was less than K_m, the decreased film resistance allowed more rapid diffusion of substrate. The enzyme, seeing substrate concentrations below that necessary to maintain V_{max}, produced more product when exposed to higher substrate concentrations.

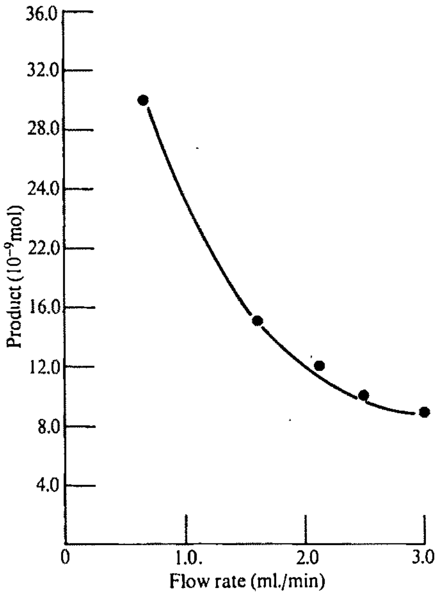

Fig. 3 Flow rate against product formation. Substrate was 2.5×10^{-4} M *p*-nitrophenylsulphate in 0.25 M $NaCO_3$ (*p*H 9.0).

The same insoluble enzyme preparation was used for all the above described experiments. The entire study took 4 weeks. At the end of this time the derivative was removed from the column and assayed. No losses of activity had occurred.

This study has shown that an arylsulphatase can be insolubilized. The insolubilized enzyme is active, stable and can be re-used many times within at least 30 days.

Possible Role of Cyclic AMP in the Short Term Regulation of Adrenal Steroidogenesis

THE most significant short term physiological effect of adrenocorticotrophic hormone (ACTH) is to increase the rate of adrenal steroid hormone synthesis and secretion[1,2]. There is a great deal of evidence for adenosine 3′,5′-monophosphate (cyclic AMP) as intracellular mediator of this acute steroidogenic response[3–9]. The following steps are probably involved[2]: ACTH increases adrenocortical adenyl cyclase activity, thus raising the intracellular concentration of cyclic AMP which in turn enhances the conversion of cholesterol to pregnenolone, normally the rate-limiting reaction. Much of the evidence for this concept comes from experiments on intact cells though the enhancement of a variety of steroid hydroxylations in cell-free adrenal preparations by cyclic AMP has been reported[10–13].

Recently Koritz *et al.*[14] found that cyclic AMP and several chemically related compounds inhibited the conversion of cholesterol to progesterone in beef adrenocortical mitochondria; and that, in rat adrenal homogenates, cyclic AMP diminished overall corticosteroid formation by inhibiting the conversion of pregnenolone to progesterone. These observations have been confirmed by others (ref. 15 and unpublished results of J. D. Jones and myself). The conversion of Δ^5-3β-hydroxysteroids to their Δ^4-3-ketosteroid products is essential in the formation of the active steroid hormones. It is catalysed by the consecutive action of a 3β-hydroxysteroid dehydrogenase (3β-HSD) and 3-ketosteroid isomerase (3-KSI) present in both the microsomal and mitochondrial subcellular fractions[15,16]. NAD^+ is the preferred cofactor for the dehydrogenase[17] while both NAD^+ and NADH are potent activators of the 3-KSI[18]. Cyclic AMP and chemically related compounds inhibit the NAD^+ and NADH-dependent activation of beef adrenocortical 3-KSI[16,18] and inhibit 3β-HSD activity competitively with respect to the cofactor NAD^+[15,16]. Cyclic AMP is the most potent inhibitor; the suppression of corticosterone synthesis in crude adrenal homogenates is observed with concentrations of cyclic AMP above 0.2 mM and the Ki for cyclic AMP inhibition of the microsomal 3-HSD activity has been estimated to range (according to my unpublished results) from 19 to 270 μM and from 121 to 192 μM[16]. In the absence or in the presence of varying concentrations of cyclic AMP 3β-HSD activity is rate-limiting in the conversion of Δ^5-3β-hydroxysteroids to their Δ^4-3-ketosteroid products[16].

These data from cell-free preparations may reflect an unsuspected inhibitory role for cyclic AMP in a relatively intact system. The experiments of Grahame-Smith *et al.*[6] on intact rats are compatible with this contention: administration of large amounts of ACTH ($\geq$ 50 mU) to rats caused an increase of the adrenal cyclic AMP to a maximum of 0.45 mmol/kg tissue. But the injection of only 2 mU of ACTH, resulting in a cyclic AMP concentration of about 25 μmol/kg adrenal tissue, proved maximally stimulatory for corticosteroidogenesis. This suggests that with larger doses of ACTH the rising adrenal level of cyclic AMP prevented a continued increase in the rate of corticosterone formation.

The following hypothesis is an attempt to reconcile the concept of cyclic AMP as intracellular mediator of the acute steroidogenic response to ACTH with its inhibitory action described here.

I propose that a small increase in plasma ACTH results in a correspondingly small increase in the intra-adrenal concentration of cyclic AMP, sufficient to enhance the conversion of cholesterol to pregnenolone and promote steroidogenesis. The ratio of C21 to C19 steroid hormone formation will depend on intracellular compartmentation and on the kinetic parameters and activities of the enzymes involved in the two pathways. With further increase in plasma ACTH the adrenal cyclic AMP level rises sufficiently to cause significant inhibition of the conversion of Δ^5-3β-hydroxysteroids to Δ^4-3-ketosteroids by competing with NAD$^+$ for binding to the 3β-HSD. Fig. 1 shows that in these conditions steroidogenesis is specifically directed towards dehydroepiandrosterone (DHEA) rather than corticosteroid and androgen formation. Thus ACTH, depending on its plasma level, may invoke at least two patterns of adrenal steroid hormone synthesis for both of which cyclic AMP is the intracellular mediator. These may overlap considerably with a gradually increasing emphasis on DHEA secretion with respect to the Δ^4-3-ketosteroids. Finally, high adrenal cyclic AMP concentrations may, by raising the intracellular level of pregnenolone, inhibit the side-chain cleavage of cholesterol and hence overall steroidogenesis.

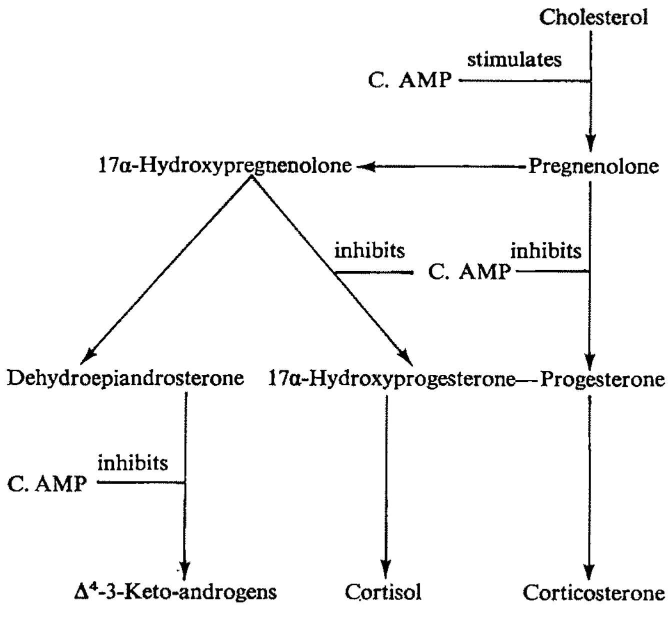

Fig. 1

The following points are relevant to a consideration of my thesis. ACTH exerts a variety of long term effects on adrenocortical function including the enhancement of specific enzyme activities[20,21] and the overall promotion of adrenal growth[22]. While these actions undoubtedly bear on the steroidogenic response to prolonged ACTH stimulation, they are not material to my hypothesis which is concerned with the acute regulation of steroid biogenesis. The validity of the hypothesis is independent of the mechanism whereby cyclic AMP stimulates the conversion of cholesterol to pregnenolone; nor is it necessarily affected by evidence[23] that 17α-hydroxyprogesterone rather than progesterone is the quantitatively more significant intermediate of cortisol biosynthesis. The validity of the hypothesis largely rests on whether, in physiological conditions, cyclic AMP reaches concentrations capable of effectively competing with available NAD$^+$ for binding to adrenal 3β-HSD. This may depend on some degree of intracellular compartmentation of cyclic AMP (ref. 16, and unpublished results of J. D. Jones and myself). Regulation of adrenal steroidogenesis by cyclic AMP is probably modified by the capacity of some C19 steroid intermediates to inhibit 3β-HSD activity[19], by the participation of steroid sulphates in biosynthesis and by the intracellular compartmentation of substrates, cofactors, and enzymes.

The hypothesis is compatible with some data derived from more physiological systems. The intravenous administration of large doses of ACTH to human subjects elicits a rapid and marked increase in adrenal DHEA secretion[24]. Urquehart *et al.*[25], in a study of the mechanisms underlying the regulation of corticosteroidogenesis, included a saturable enzyme step subsequent to cholesterol side-chain cleavage. According to my hypothesis stimulation by ACTH could cause the adrenal concentration of pregnenolone and 17α-hydroxypregnenolone to rise to levels at which zero order kinetics would hold for their conversion into their respective Δ^4-3-keto products.

The biological significance of the hypothesis remains to be determined. In species such as rodents, lacking significant 17-hydroxylase activity, adrenal dehydroepiandrosterone secretion would be negligible regardless of adrenal cyclic AMP levels. In other species, including man, DHEA (sulphate) secretion may be considerable at high plasma ACTH and adrenal cyclic AMP concentrations. As well as possessing insignificant intrinsic androgenic activity DHEA seems to be a limited peripheral precursor of the more potent sex hormones[26], except in the placenta[27]. Thus the diversion of steroid biosynthesis towards DHEA production may be a means of avoiding excessive and inappropriate androgen, and possibly corticosteroid, secretion in response to ACTH. Yang and Deal[28] have reported that cyclic AMP and related compounds inhibit yeast glyceraldehyde 3-phosphate dehydrogenase by a mechanism analogous to cyclic AMP inhibition of 3β-HSD. The direct inhibition of key dehydrogenases by cyclic AMP may have hitherto unsuspected significance in metabolic regulation.

Synthetic Compounds with Toxic Properties similar to those of Pyrrolizidine Alkaloids and their Pyrrolic Metabolites

FOR the first time, some of the toxic effects of unsaturated pyrrolizidine alkaloids on rats have been reproduced by dosing animals with synthetic compounds. Many of the naturally occurring hepatotoxic alkaloids are esters of the isomeric amino-alcohols retronecine or heliotridine with various branched chain hydroxy-acids[1]. The most toxic alkaloids are cyclic diesters of retronecine[1], which are particularly resistant to enzymic hydrolysis. Because hepatotoxicity of the pyrrolizidine alkaloids has been associated with the metabolic conversion of the pyrroline to a pyrrole ring[2,3], with retention of the ester groups[4], it was expected that simpler pyrroline esters would have similar toxic properties provided that the ester groups were resistant to enzymic hydrolysis.

Of the compounds I have prepared and tested, the most effective are carbamate esters of 1-methyl-2,3-*bis*-hydroxymethyl-3-pyrroline. The N-ethyl carbamate diester (I) of this amino-alcohol is rather more toxic than the natural alkaloid monocrotaline (IV). In preliminary experiments, pyrrolic metabolites were demonstrated[5] in the livers, lungs and urine of male rats 2 h after intraperitoneal injection of this synthetic compound. Most animals given doses of more than 60 mg/kg body weight died 2–6 days later and had bloodstained ascites and massive haemorrhagic centrilobular liver necrosis. Histologically, this was characteristic of the type of damage caused by pyrrolizidine alkaloid poisoning[6]. Similar effects were seen after oral administration of the compound. Rats surviving for 3 weeks had the characteristic giant liver cells (megalocytes)[7] and these were abundant in livers of rats which had been given the compound intraperitoneally (30–40 mg/kg) at the age of 4 days. After very large doses (160–250 mg/kg) the animals usually died on the second or third day with their chests full of pale yellow fluid. It has been suggested[8,9] that lung damage due to pyrrolizidine alkaloids may be caused by some of the metabolite formed in the liver escaping to the lungs.

The analogous diacetyl and di-isovaleryl esters (II and III) were not toxic to rats at much larger doses than the carbamate, and were not metabolized to significant amounts of pyrrole derivatives. The choice of carbamate esters was made from previous experience with semisynthetic retronecine diesters. Hepatotoxicity has been demonstrated[10] in esters such as di-isovaleryl retronecine (V)[11] when doses larger than 250 mg/kg were administered to rats, but diacetyl retronecine (VI) was hepatotoxic only in much larger doses and after the animals had been treated with an esterase inhibitor[9]. It was thought that rapid hydrolysis by esterases to the highly water soluble amino-alcohol might be responsible for the low toxicities of semisynthetic esters and that carbamates might be more resistant to such hydrolysis, or even inhibitory to esterases[12]. The semisynthetic N-ethyl carbamate diester of retronecine (VII) was therefore prepared, and its toxicity to the rat was similar to that of monocrotaline (IV)[13]. The synthetic carbamate (I) subsequently proved to be even more toxic.

Characteristic toxic effects in the lungs of rats have been found after intravenous injection of pyrrolic esters derived from natural pyrrolizidine alkaloids, such as monocrotaline pyrrole[14], and semisynthetic esters such as diacetyl retronecine pyrrole[9]. We have now obtained the same effects using the entirely synthetic compound, 1-methyl-2,3-diacetoxymethyl pyrrole (VIII). Injections of 5–12 mg/kg of this compound into the tail veins of rats of either sex often caused death after 20–35 days and produced changes in the lungs similar to those described earlier for monocrotaline pyrrole[14]. Some centrilobular liver necrosis was also seen. Larger doses caused massive pleural effusions and death within a few days.

The results described here are consistent with the view that chemically reactive pyrrolic metabolites are responsible for cytotoxic effects of pyrrolizidine alkaloids, and show for the first time that such effects can be caused by compounds with a single five membered ring. It follows that studies of the types of experimental liver and lung lesions described here need no longer depend on supplies of natural pyrrolizidine alkaloids. Chemically modified and radioactive labelled compounds will be more readily available for investigations of mechanisms of toxic action. Tumour-inhibitory activity has been observed with some of the natural alkaloids[15] and their pyrrolic derivatives[3], and the use of synthetic analogues might enable this property to be exploited more effectively. Further studies of the toxic and other effects of these and related synthetic compounds are in hand and will be reported in detail elsewhere.

I thank Drs J. M. Barnes and W. H. Butler for help with the pathology and R. Jones for technical assistance.

Tolerance to Opioid Narcotics: Time Course and Reversibility of Physical Dependence in Mice

REPEATED administration of an opiate narcotic leads to the tolerant-dependent state. Previous communications[1,2] from this laboratory have described the relationship between the degree of tolerance in mice and the dose, interval and duration of exposure to an opiate. Recently, jumping behaviour elicited by the opiate antagonist, naloxone, was shown to be a sensitive indicator of the degree of dependence[3]. We have used this method to follow the time courses of the onset and reversal of dependence in various conditions of exposure to opiates.

Male Swiss-Webster mice weighing 25–30 g were used. Water and Purina laboratory food were freely available. Levorphanol tartrate, a synthetic congener of morphine, was supplied by Hoffmann-LaRoche Inc. Naloxone hydrochloride was a gift of Endo Laboratories and morphine alkaloid was purchased from Mallinckrodt Chemicals Inc. Doses are expressed in terms of the free bases. All injections were intraperitoneal.

Physical dependence on morphine was produced by implanting a specially formulated 75 mg morphine pellet[4], without anaesthesia, in the subcutaneous tissue of the back. Animals so implanted display analgesia and vigorous running activity for less than 24 h. Release of morphine from the pellet proceeds linearly for longer than the time of our experiments[5].

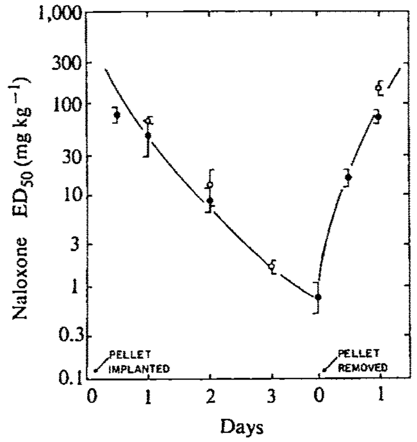

Fig. 1 Development and reversibility of physical dependence. The ED_{50} for naloxone-induced jumping is plotted on a logarithmic scale against time. Mice were implanted with 75 mg morphine pellets. Groups were tested with naloxone at various times, then discarded; pellets remained in place during testing. After 3.7 days pellets were removed from all remaining animals in order to follow the recovery process and 2 days later groups of mice were re-implanted on the opposite side with fresh pellets, which were also removed after 3.7 days. Solid circles represent the first cycle of dependence and recovery, open circles represent the second cycle. Standard errors of the ED_{50} estimates are shown by brackets above and below each data point. In these experiments 325 mice were implanted initially; each point is based on twenty-four to thirty-three animals.

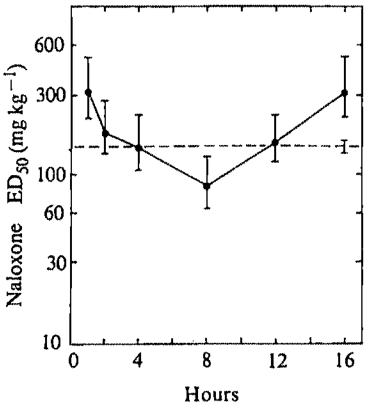

Fig. 2 Initiation of physical dependence by a single dose of levorphanol. At time zero, mice were given a single intraperitoneal 20 mg kg^{-1} levorphanol injection. Groups were tested with several doses of naloxone at various times thereafter to determine the ED_{50} for precipitated jumping. The dashed line indicates the ED_{50} for naloxone-induced convulsions in control mice. Each ED_{50} above the dashed line is an extrapolation from the lower dose segment of a quantal log dose-response curve obtained at the given time. Standard errors of the ED_{50} estimates are shown by brackets above and below each data point. Each point is based on forty-five animals.

Naloxone was used to precipitate withdrawal jumping, as described by Maggiolo and Huidobro[5] and Way *et al.*[3]. The ED_{50} (median effective dose) of naloxone was determined according to Litchfield and Wilcoxon[6] or by the more economical "up and down" method of Dixon[7], in which five mice were injected and placed on the platform together. If a mouse jumped off within 10 min, the dose for its replacement was halved; otherwise, the dose for its replacement was doubled. Thus, five replicate series were obtained. Groups of mice were tested at different times, but each group was tested once only, then discarded.

In untreated mice, no dose of naloxone would induce jumping, but in opiate-dependent mice, doses of about 150 mg kg^{-1} or less were effective: the smaller the degree of dependence, the higher the necessary dose of naloxone. The method was limited by the fact that naloxone itself, in dependent as well as untreated mice, causes convulsions at high doses (ED_{50} = 150 ± 13 mg kg^{-1} in untreated mice) so that a very small degree of dependence could not be measured.

After implantation of a morphine pellet, the sensitivity to naloxone became progressively greater for more than 3 days (Fig. 1). The time course of the approach to a steady state is evidently measured in days, although in these experiments a constant level of dependence was not quite reached. The process was completely reversible after removal of the pellet, and the return to normal was complete in 24 h. A group of the same animals was re-implanted and the entire cycle of onset and disappearance of dependence observed. The high degree of dependence produced in the first cycle clearly had no modifying effect on the second cycle, which was, within the limits of experimental error, identical to the first. The disappearance of dependence so much faster than it develops has interesting theoretical implications[8–10].

A single moderate dose of levorphanol (20 mg kg^{-1}) produced a definite but small degree of dependence (Fig. 2). (The ED_{50} of levorphanol for running activity and analgesia is 2.3 mg kg^{-1}; see ref. 1.) The process is evidently initiated immediately, reaches its peak after about 8 h, then wanes and disappears after 16 h. Naloxone can elicit jumping 16 h after a single injection although levorphanol has a very short half-life—less than 1 h—in plasma and brain of the mouse (unpublished observations of A. G.). As might be expected, injection of the same dose of levorphanol every 12 h produced only a small degree of dependence at the steady state, whereas injection every 4 h produced an increasing degree of dependence (Fig. 3).

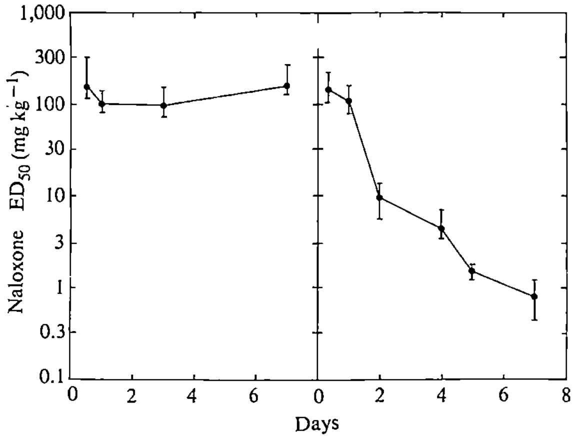

Fig. 3 Development of physical dependence on 12 h (left) and 4 h (right) schedules of levorphanol injections (20 mg kg^{-1}). Groups were tested with several concentrations of naloxone 12 h or 4 h, respectively, after the previous injection of levorphanol to determine the ED_{50} values for naloxone-induced jumping. Symbols are as in Fig. 2.

We have shown here that in the mouse, a single dose of opiate produces a certain quantum of physical dependence, which dissipates entirely in about 24 h. A small degree of dependence can also be produced by a single dose of opiate in the spinal dog[11]. In our experiments, frequent injections of levorphanol or implantation of a morphine pellet caused a cumulative build up of dependence. Injections at a long enough interval caused no build up of dependence, regardless of the duration of administration of the drug. These findings agree with our observations on tolerance[1,2]: the frequency of administration of a fixed dose controls the level of the steady state attained. Anecdotal evidence suggests a similar phenomenon in human narcotic addiction; tolerance and dependence probably do not develop at dose frequencies lower than about 0.5–1.0/day[12,13].

We have also shown that physical dependence in the mouse, like tolerance, is completely and rapidly reversible, and that one cycle of dependence and recovery does not modify the course of a subsequent cycle. On the other hand, Wikler and Pescor[14] demonstrated long lasting residual effects of an addiction cycle in rats. Goldberg and Schuster[15] showed, in monkeys, that naloxone could precipitate certain physiological disturbances months after morphine withdrawal, and in man Martin and co-workers[16,17] found that abnormalities similar to those of the withdrawal syndrome persisted for months after the principal withdrawal effects had terminated. We are not able to explain the differences between these results and our own.

This investigation was supported by a research grant from the National Institute of Mental Health and by a training grant from the National Institute of General Medical Sciences. We thank Dr R. D. Gibson for morphine pellets. (Some of the findings reported here were the subject of a preliminary communication[18].)

Serological Demonstration of H-Y (Male) Antigen on Mouse Sperm

WE have recently overcome certain technical difficulties in applying the cytotoxicity test to mouse spermatozoa and have been able to show directly that H-2 antigens are expressed on these cells[1], thus confirming less direct evidence leading to the same conclusion[2]. We have since applied the cytotoxicity test to sperm with antisera directed against a number of other systems of mouse alloantigens, TL[3], θ[4], Ly-A[5] and Ly-B[5], but none of these has given a positive reaction with sperm. This is not surprising because these are all "differentiation antigens"[6] expressed primarily on lymphoid cells. Another antigenic system which distinguishes one mouse from another is H-Y. The H-Y antigen is carried by male cells only and is responsible for the rejection of male tissues by females of the same inbred strain[7].

In the case of H-Y, in contrast to the other antigenic systems referred to above, there has so far been no conclusive serological demonstration of the antigen *in vitro*. This obviously limits further analysis of the H-Y system and leaves much uncertainty as to the nature of the anti H-Y immune response in terms of humoral and cellular immune factors.

The following data establish three things: (*a*) H-Y antigen can be detected serologically by the cytotoxicity test *in vitro*.

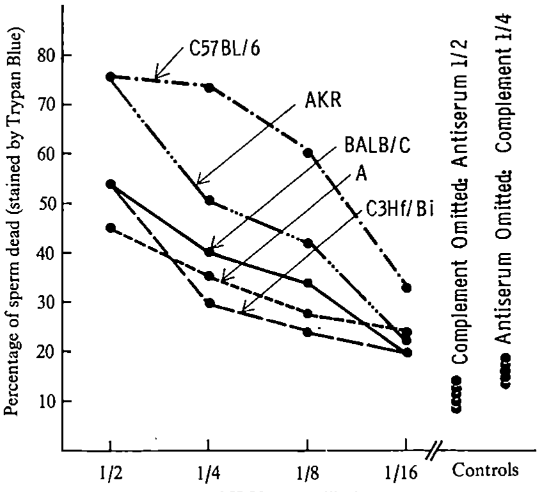

Fig. 1 Detection of H-Y antigen on epididymal sperm of A, C57BL/6, C3Hf/Bi, BALB/c and AKR mice by the cytotoxicity test with serum of C57BL/6 female mice which had rejected C57BL/6 male skin grafts.

(*b*) H-Y antigen is present on sperm as suggested by indirect evidence *in vivo*[8]. (*c*) Very probably, at least some *X*-bearing sperm as well as *Y*-bearing sperm carry H-Y antigen, indicating that at least some of the surface membrane of sperm is conserved from antecedent cells of an earlier stage in differentiation when both *X* and *Y* chromosomes were present in each cell.

Serum for the cytotoxicity test (referred to as anti H-Y serum) was obtained from C57BL/6 female mice 5–14 days after they had rejected a fourth or fifth skin graft from C57BL/6 males. Complement for the cytotoxicity test was provided in the form of serum from individual rabbits that had been selected for both low toxicity to mouse thymocytes and a high level of complement[9]. Before use, this selected rabbit serum was absorbed twice with mouse cells (eight parts to one by volume), including cells from the testis, in the absence of free calcium, to remove natural hetero-antibody. The object of excluding calcium is to prevent loss of complement during absorption[9].

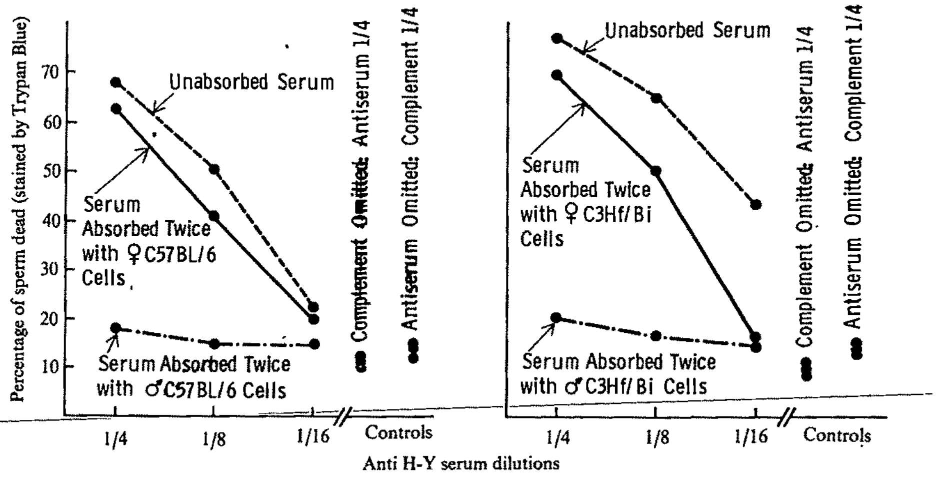

Fig. 2 Specificity of sperm lysis by anti H-Y serum(¼). Titration of cytotoxic anti H-Y serum absorbed twice with either male or female cells, and then tested on C57BL/6 sperm. First experiment (left): absorption with C57BL/6 cells; second experiment (right): absorption with C3Hf/Bi cells.

Mice of the inbred strains C57BL/6, A, AKR, BALB/c and C3Hf/Bi were obtained from colonies maintained by one of us (E. A. B.). Epididymal sperm were obtained by cutting the entire epididymis into slices in a few drops of phosphate-buffered saline (*p*H 7.0) containing 0.5% fructose and 5% foetal calf serum. After 5 min, the medium containing free sperm was pipetted off and the suspension kept at room temperature until use[1].

Table 1 Cytotoxicity Tests on Mouse Epididymal Sperm with anti H-Y Serum

Strain donating sperm	Experiment (i)	(ii)	(iii)	(iv)	(v)	(vi)	(vii)	(viii)
		% sperm dead (stained by trypan blue)*						
C57BL/6	71	64	73	81	78	76	88	68
AKR					75			
A	37	57	45	62				
BALB/c	54	55						
C3Hf/Bi	54							

Summary of eight experiments: every test included a control in which complement was omitted and another with antiserum omitted; these showed consistently fewer than 18% sperm dead.

* In antiserum diluted by one half, at which dilution the greatest proportion of sperm were killed (see Fig. 1; undiluted antiserum was not tested).

Doubling dilutions of anti H-Y serum (half to one-sixteenth) were prepared for the cytotoxicity test. Equal volumes (0.05 ml.) of (*a*) diluted anti H-Y serum, (*b*) sperm suspension ($4–5 \times 10^6$/ml.) and (*c*) absorbed rabbit serum diluted one quarter, were incubated for 45 min at 37° C. Sperm counts were made in a haemacytometer after addition of 0.1 ml. of a freshly prepared solution of trypan blue (stock solution of 1% trypan blue in distilled water, diluted immediately before use with 42.5 g/l. of NaCl, one part in five, to render it isotonic).

The results summarized in Table 1 show that sperm from all strains tested were lysed by anti H-Y serum. Representative tests are illustrated more fully in Fig. 1. Sperm from strains A, C3Hf/Bi and BALB/c were less susceptible than C57BL/6 sperm indicating either (*a*) that there are strain differences in the amount of H-Y antigen on sperm, or (*b*) that these strains have different alleles at the H-Y locus[10] so that their H-Y antigens cross-react but are not identical. Known strain differences in rate and incidence of male skin rejection by females may be accounted for on these lines, and this is now amenable to serological investigation.

To confirm that the cytotoxic reaction was specific for H-Y antigen, aliquots of anti H-Y serum (diluted one-quarter) were absorbed twice with equal numbers of either male or female C57BL/6 cells from spleen, lymph node, and thymus (four volumes serum to one volume packed cells for 30 min in an ice bath), and the absorbed sera were then tested on C57BL/6 epididymal sperm. There was only minimal loss of cytotoxic activity after double absorption with female cells, no more than is to be expected from non-specific causes, and essentially complete loss of activity after double absorption with male cells: see Fig. 2, which includes a similar experiment in which C3Hf/Bi cells were used for absorption.

After due allowance for background levels of non-specific death of sperm during the cytotoxicity test, it is clear that the percentage of sperm specifically lysed by anti H-Y serum often exceeds 50. It is probable therefore that as in the case of H-2 (ref. 1) the surface phenotype of at least some sperm reflects the diploid complement of their precursor cells, rather than their own haploid constitution. It must be emphasized that there is no justification for assuming that cells surviving a cytotoxicity test, particularly in a relatively weak system like H-Y, necessarily lack the antigen being tested for; the probability of lysis for each cell of a uniform population probably depends on many randomly variable factors. It would therefore be rash to conclude that the surviving sperm are H-Y$^-$.

Anti H-Y sera were not positive in cytotoxicity tests with male thymocytes, lymph node cells or spleen cells. Nevertheless the presence of some H-Y antigen on these cells, or of some H-Y$^+$ cells in these populations, is implied by their capacity to absorb H-Y antibody (Fig. 2) and by tests *in vivo*[11–13]. In further absorption experiments, we have found that each of these cell populations individually is H-Y$^+$; and we shall report elsewhere that the cytotoxicity test is positive with enzymatically dissociated male (but not female) epidermal cells from skin.

Effects of Steroid Pharmaceuticals on Plasma Zinc

ORAL contraceptives have been found to cause large changes in the levels of copper and iron in the blood[1]. Their effects on the level of plasma zinc, however, are uncertain, for although in one case it was reported that the level increased[2], in another significant decreases were found[3]. Apart from testosterone propionate, which was found to increase the level of plasma zinc[4], other widely used steroid pharmaceuticals have not been investigated. We therefore undertook to determine the effects of such substances, including oral contraceptives, on the plasma zinc of healthy human subjects.

All volunteers were free of any obvious disease and were of families with no histories of conditions likely to influence the study. None had taken steroids before. Fasting blood samples were obtained by venepuncture on several occasions before the steroids were taken. No pharmaceuticals, other than the substance under test, were taken during the trial period. For the women in the study, the day of the menstrual cycle was recorded at the collection of each sample.

The steroids and the daily dose levels used were ethinylestradiol (0.05 mg), norethisterone acetate (1.0 and 0.5 mg), ethinylestradiol plus norethisterone acetate ('Minovlar' 0.05 mg + 1.0 mg), *d*(–)-norgestrel (1.0 mg and 0.25 mg), *d*(–)-norgestrel plus ethinylestradiol (Eugynon, 0.25 mg + 0.05 mg), mesterolone (Proviron, 100 mg), and prednisolone (5 mg and 10 mg). The steroids were taken once a day at the same time each day, for 30 consecutive days, except for the oral contraceptives which were taken for 21 days, and for prednisolone which was taken for only 10 days. Twenty-five subjects were investigated, twenty women and five men, ranging in age from 18 to 38 yr. Some received two courses of treatment separated by a suitable interval. Zinc was assayed in plasma by atomic absorption spectrophotometry, using methods similar to those of Davies *et al.*[5].

Table 1 Effects of Steroids on Plasma Zinc

Steroid	Daily oral dose (mg)	Sex	Plasma zinc (μg/100 ml., mean ±s.d.)	*P*
None	None	F	99±14	—
None	None	M	98±15	—
Ethinylestradiol	0.05	F	83±16	<0.01
Norethisterone acetate	1.0	F	99±15	N.S.
Norethisterone acetate	5.0	F	89±15	<0.02
Ethinylestradiol plus norethisterone acetate	0.05+ 1.0	F	82±15	<0.01
d(–)-Norgestrel	1.0	F	98±14	N.S.
d(–)-Norgestrel	0.25	F	100±15	N.S.
Ethinylestradiol plus *d*(–)-norgestrel	0.05+ 0.25	F	84±12	<0.01
Mesterolone	100	M	100±17	N.S.
Prednisolone	5	M	98±16	N.S.
Prednisolone	10	M+F	101±15	N.S.

The results are given in Table 1. The significance of any changes was assessed by a *t* test of each set of results against the control values. There was no difference in plasma zinc levels between untreated men and women. The stage of the menstrual cycle had no influence on the levels. There was no significant difference between concentrations in blood collected during the follicular or luteal phases, or at the time of menstruation. This finding strongly suggests that changes in endogenous steroid hormones are without effect on plasma zinc. Of the various steroid pharmaceuticals, only oestrogenic preparations had any significant action. Ethinylestradiol, 0.05 mg, given alone or in combination with a progestogen, produced a marked decrease in plasma zinc. This is in contrast to the effect of this steroid on blood iron and copper, both of which are increased[1].

The largest dose of norethisterone acetate (5 mg) also produced a small decrease in plasma zinc; this could be a consequence of the action of oestrogenic metabolites of this progestogen formed *in vitro*. Ethinylestradiol has been identified as a metabolite in the human[6]. That the effect is not due to progestogenic influences is shown by the lack of effect of the other progestogen, norgestrel. The latter is more than five times as progestogenic as norethisterone acetate, but lacks any significant oestrogenic metabolites[7].

Neither prednisolone nor the oral androgen mesterolone had any effect in contrast to the reported action of testosterone propionate on plasma zinc in rats[4]. To determine whether the action of ethinylestradiol on plasma zinc is reversible, we studied women who had ceased to take the steroid. Normal values were restored after 15 to 20 days. We have also studied levels of plasma zinc in a group of women which had taken oral contraceptives continuously for 5–8 yr. They also showed significantly depressed plasma zinc levels, indicating that the body cannot adopt to exogenous oestrogens and restore the level to normal.

The clinical significance of chronically low plasma zinc is unknown, but zinc has been implicated in a number of liver diseases and in diabetes mellitus. Both these have been suspected as long term side effects of oral contraceptives.

Meiotic Studies of the Ejaculated Seminal Fluid of Humans with Normal Sperm Count and Oligospermia

So far, all known studies of human meiosis have been performed on germinal cells obtained from testicular biopsies[1,2]. As this involves a surgical procedure to obtain the material, we wish to draw attention to the statement, first made by Michael and Joel[3], that immature germ cells can regularly be seen in the seminal fluid of the human male. We have found that in smear preparations of the ejaculate of subjects with a normal sperm count, nearly 3% of the cells consist of spermatogonia, spermatocytes and spermatids (Table 1), the maximum percentage being 5%. A similar result was obtained by Heinke and Doepfmer[4]. As the sperm count decreases, however, the percentage of immature cells generally increases and, in some pathogenic cases, the percentage may be 40% or more[5]. We have characterized the cells in material in which a high percentage of the cells were immature as a preliminary to cytogenetic studies of human male meiosis.

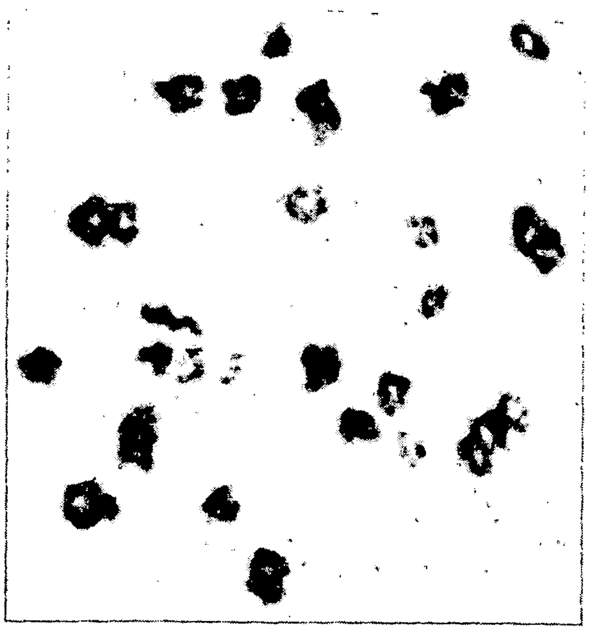

Fig. 1 Primary spermatocyte at diakinesis, from the ejaculated seminal fluid of a human male with oligospermia (× 1,800).

The cells were stained for viability by the trypan-blue method[6]. In both normal and oligospermia seminal fluid, 75–85% of the cells—the viable cells—remained unstained. Furthermore, autoradiographs of spermatogonia and preleptotene spermatocytes indicated that some could incorporate tritiated thymidine. Preparations of the meiotic chromosomes in diakinesis and metaphase-I were made after hypotonic treatment by the air-dry method of Evans *et al.*[7] (Fig. 1). The best results with cells at the pachytene stage were achieved by the squash method without any pretreatment with the fixative proposed by Annerén *et al.*[8]. The relative frequency of these different stages varies in each case but leptotene and pachytene cells are predominant, possibly because of the long duration of the meiotic prophase[9]. Nevertheless, cells in diakinesis occur in oligospermia preparations and also in the ejaculate of normal males. These preliminary results suggest that the seminal fluid is a useful source of immature germ cells for cytogenetic studies of human male meiosis.

Table 1 Mean Percentage of Immature Germ Cells in the Ejaculated Seminal Fluid of Human Males with Different Sperm Qualities

Sperm quality	No. of sperm (million/ml.)	No. of subjects investigated	Spermatogonia (%)	Spermatocytes (%)	Spermatids (%)	Total (%)
Normospermia	≥ 40	139	0.5	0.3	2.0	2.8
Oligospermia I	$\geq 5 < 40$	93	2.0	1.4	4.4	7.8
Oligospermia II	$\geq 1 < 5$	24	7.0	3.4	11.0	21.4

Mandibular Gland Secretion of Larvae of the Flour Moth, *Anagasta kuehniella*, contains an Epideictic Pheromone and elicits Oviposition Movements in a Hymenopteran Parasite

Hassell and Huffaker[1] demonstrated some density-dependent regulation of numbers in populations of the flour moth, *Anagasta kuehniella* (Zeller). Fighting between newly hatched larvae[2] contributes to the regulation of numbers in this species but is not the only controlling mechanism: Smith[3] showed that crowding from the end of the first instar onwards led to delayed emergence of adults and a reduction in body weight. Since smaller moths lay few eggs[4], both these effects would contribute to the density-dependent regulation of numbers in succeeding generations. I describe here a mechanism which could bring about these effects. I suggest that last-instar larvae of *A. kuehniella*, when they meet, deposit on the substratum drops of secretion from their mandibular glands; and that the response of other last-instar larvae to this secretion results not only in the regulation of the total numbers of

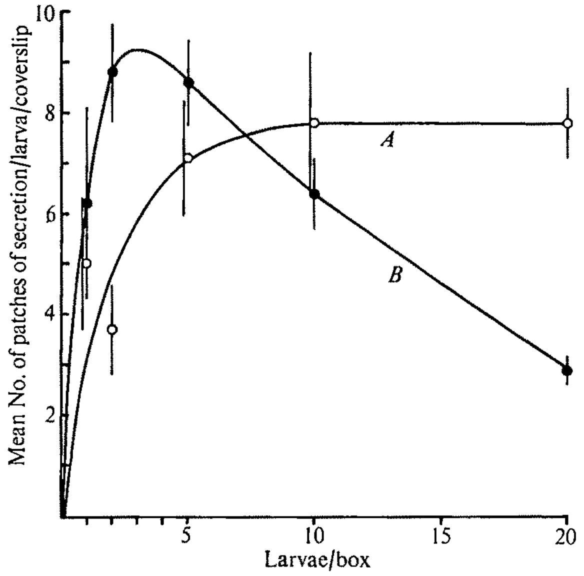

Fig. 1 Mean numbers of patches of mandibular gland secretion per larva on coverslips that were on the floors of boxes in which 1, 2, 5, 10 or 20 larvae were confined for 1 h (*A*) or for 24 h (*B*) (experiment 2). Each vertical line represents twice the standard error.

A. kuehniella in a finite system (as studied by Smith[3]), but also in the control of the dispersion of individuals within that system.

The mandibular glands of last-instar larvae of *A. kuehniella*, like those of *Galleria mellonella* (L.)[5], are tubular structures lying folded in the haemocoele. One opens at the base of each mandible. They contain a clear oily fluid which is deposited in droplets on the substratum beside the silken thread and can be stained red with Nile blue inside the gland or after deposition. Larvae that meet each other head to head show a characteristic response involving sudden withdrawal and the separation of the mandibles. My experiment 1 showed that this behaviour is sometimes (and perhaps always) accompanied by the release of mandibular gland secretion, which is sometimes deposited on the substratum. In experiment 1*A*, a larva was allowed to crawl over a 6 cm square surface marked with 1 cm squares, and at recorded locations the withdrawal response was elicited by touching it, head to head, with another larva held in forceps. After three, four or five such encounters the surface was treated with Nile blue and examined for red-staining material. In ten trials of this kind, involving forty-two encounters, all but one of the thirty-six patches of red-staining material were within 1 cm of meeting places or of the places where the larvae were put down at the beginning of each trial; larvae often made the withdrawal response when first put down. Another ten trials (experiment 1*B*), in which the response was elicited by prodding with forceps instead of by contact with another larva, gave similar results; the larvae were prodded thirty-three times, and all but two of the twenty-three patches of secretion were within 1 cm of a place where a larva had been prodded, or put down at the beginning of a trial. Evidently the withdrawal response, elicited by mechanical stimulation or by contact with another larva, often leads to the deposition on the substratum of secretion from the mandibular glands.

Fig. 1 shows the results of experiment 2 in which larvae were confined for 1 h (*A*) or 24 h (*B*), singly or in groups, in standard boxes of internal dimensions 56×38×13 mm. On the floor of each box was a coverslip (22×50 mm) which was subsequently treated with Nile blue so that patches of red-staining secretion on its surface could be counted. The number counted was assumed to be proportional to the number of patches on the inner surfaces of the box. Fig. 1*A* shows that individual larvae released more secretion when crowded than when alone, as would be expected if the relase of secretion is stimulated by meetings between larvae. Fig. 1*B* also shows this effect at low densities, although at high densities the number of patches of secretion appears smaller after 24 h than after 1 h, because crowded larvae, walking over the coverslips, picked up the secretion on their bodies. Dissections of larvae that had been crowded for 24 h showed that the percentage with one or both mandibular glands shrivelled and empty increased with the density of crowding from 8% (or 25) for solitary larvae to 48% (or 255) for larvae in groups of twenty per box.

Experiment 3 concerned the response of last-instar larvae of *A. kuehniella* to crowding (3*A*) and to mandibular gland secretion of other last-instar larvae (3*B* and *C*). The response was assessed in terms of the duration of the wandering period, during which fully fed larvae crawl about, away from their food, and which ends with the spinning of the cocoons in which the larvae will pupate. For each experiment a batch of larvae was selected from their stock cultures on the first day of their wandering stage. They were kept in standard transparent boxes at 25±0.5° C and for 10 (3*C*) or 12 (3*A* and 3*B*) days they were examined every morning so that the dates of cocoon-spinning and pupation could be recorded. Individuals (about 1–4%) that failed to spin up during the 10 or 12 day experiments were not included in the results. In each experiment the patterns of variation in the dates of cocoon-spinning and of pupation were alike, and only the dates of pupation are shown here.

In experiment 3*A* larvae were kept singly or "crowded" in groups of two, five, ten or twenty per box, and the results (Fig. 2*A*) show a pattern that is repeated in the results of experiments 3*B* and 3*C*: the larvae at an intermediate density pupated sooner than those that were either at very low density or very densely crowded. The results of experiment 3*B* (Fig. 2*B*) indicate that this effect of crowding was mediated

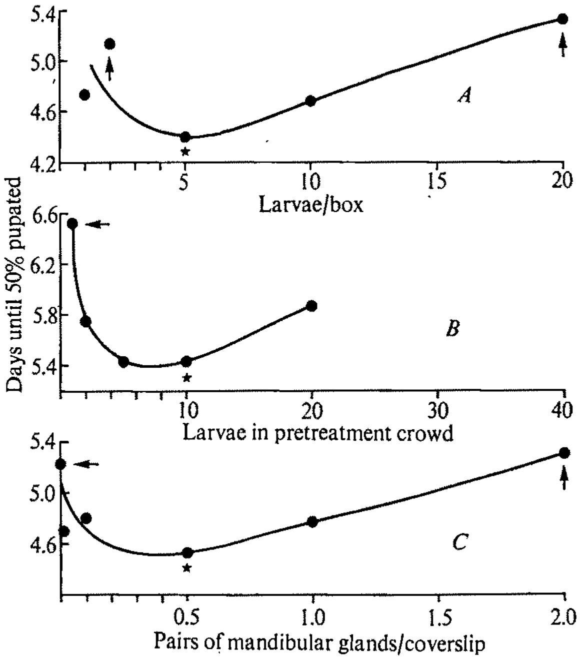

Fig. 2 Results of experiment 3. *A*, Effect of crowding on the timing of pupation. *B*, Effect of coverslips, previously exposed to crowds of larvae, on the timing of pupation of isolated larvae. *C*, Effect of coverslips, treated with ether extract of mandibular glands, on the timing of pupation of isolated larvae. The values on the ordinate are derived from cumulative plots, smoothed by a moving average of three, of the number of new pupae against time. The points marked with a star differ significantly from those marked with an arrow on the same graph ($P<0.0075$ in *A*; $P<0.05$ in *B*; $P<0.025$ in *C*; one-tailed Mann–Whitney U test).

by something deposited ~~on the~~ substratum by crowded larvae. Each larva in this experiment was kept alone in a standard box, on the floor of which was a 22×50 mm coverslip previously exposed for 1 h in a similar box containing one, two, five, ten or twenty larvae (the pre-treatment crowd). Evidently the size of the pre-treatment crowd influenced the timing of pupation of the isolated larvae subsequently exposed to the coverslips, in such a way that pre-treatment crowds of moderate size resulted in earlier pupation than did larger or smaller pre-treatment crowds. The coverslips that had been exposed to these crowds of larvae carried deposits of silk and frass as well as mandibular gland secretion. Experiment 3*C* provides evidence that it was the mandibular gland secretion that transmitted the crowding stimulus from the pre-treatment crowd to the isolated larvae.

In experiment 3*C* the larvae were again kept isolated in standard boxes. On the floor of each box was a 22×50 mm coverslip on which had been deposited a drop of ether in which had been ground mandibular glands dissected from last-instar larvae. On the coverslips of the controls drops of pure solvent were deposited. In this experiment (Fig. 2*C*) changes in the number of pairs of mandibular glands per coverslip affected the timing of pupation as changes in the degree of crowding did: the larvae pupated sooner in the presence of moderate quantities of mandibular glands than they did in the presence of larger or smaller quantities. In one of the three replicates of experiment 3*C*, each pupa was weighed on its first day after pupation, and the mean weights of the new pupae were calculated for each day. Fig. 3 shows that individuals that pupated later formed lighter pupae than did those pupating earlier.

Experiments 1 and 2 show that the amount of mandibular gland secretion deposited on the substratum is a measure of the density of crowding, and experiment 3 shows that in the presence of appropriate quantities of mandibular gland secretion, isolated larvae responded as though they were crowded. The response mediated by the secretion of the mandibular glands may help to regulate the density towards an "optimal" value, equivalent to about five larvae per box in the conditions of these experiments. Larvae at densities close to this value spin up and pupate relatively quickly, whereas those at higher or lower densities wander for a longer time, thus increasing their chances of reaching an area where the population density is "optimal" before spinning up.

The "overcrowding" effects, expressed by the right hand limbs of the curves in Fig. 2, will regulate the density of the population in three ways: by controlling the spatial distribution of individuals within their habitat, encouraging emigration from crowded situations; by lengthening the generation time of individuals in crowded populations; and by reducing the fecundity of the females crowded as larvae. Fecundity is reduced insofar as wandering larvae spin silk and lose weight as they go, so that those pupating later are, on average, lighter than those pupating earlier (Fig. 3); and lighter flour moths lay fewer eggs than do heavier flour moths[4]. In the presence of the ichneumonid parasite *Venturia canescens* (Grav.) another density-regulating effect comes into play. The mandibular gland secretion of *A. kuehniella* stimulates oviposition movements in the parasite (discussed later), and a larger proportion of the host caterpillars are parasitized in a crowded population than in an uncrowded one[6].

The secretion of the mandibular glands of *A. kuehniella* falls within the definition of a pheromone given by Karlson and Butenandt[7]. And since it functions in the regulation of population density, controlling the dispersion of individuals, the duration of larval development and the fecundity of the moths, it can be described as an "epideictic"[8] pheromone.

Venturia canescens, an ichneumonid parasite of *A. kuehniella*, responds to a component of the mandibular gland secretion of its host by making a series of ovipositional movements. When a female of *V. canescens* oviposits in a larva of *A. kuehniella* she taps her antennae against the host, unsheaths her ovipositor so that the tip points forwards and downwards, and then makes jabbing movements which, if they penetrate the host's cuticle, may result in the release of an egg. In the absence of a suitable host this series of actions is interrupted at some point before the release of the egg. In my experiments between thirty and fifty adult females of *V. canescens* were confined in a dish with a small rectangle of filter paper to which the materials under test had been applied as two spots placed symmetrically about 2.5 cm apart. For 10 min I recorded the number of "jabbing sessions" directed at each spot. A "jabbing session" involved unsheathing the ovipositor, making one or more jabbing movements, and returning the ovipositor to its resting position. For each of the ten trials in experiment 4*A*, five last-instar larvae of *A. kuehniella* were separated into (i) the heads with the mandibular glands and the silk glands attached, and (ii) the rest of the bodies. The two spots presented to the parasites consisted of breis made from these two portions of the larvae. Ninety-two per cent of the parasites' jabbing sessions were directed at the spots containing the heads, mandibular glands and silk glands (Table 1). In each of the ten trials in experiment 4*B* one crushed pair of mandibular glands was tested against the crushed pair of silk glands from the same last-instar larva. (The head, contaminated with the products of both glands, was discarded.) The mandibular glands elicited 95% of the jabbing sessions (Table 1).

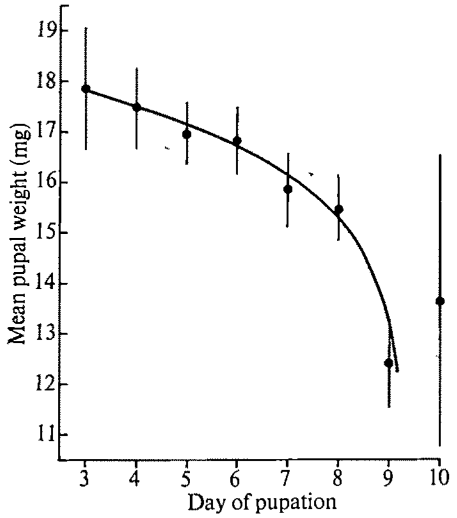

Fig. 3 Mean weights of pupae formed on successive days of experiment 3*C*. Each vertical line represents twice the standard error.

Table 1 Results of Experiment 4

	Material presented to parasites	No. of jabbing sessions
A	Head + glands of *A. kuehniella* larvae	784 (92%)
	Rest of bodies of *A. kuehniella* larvae	69 (8%)
B	Mandibular glands of *A. kuehniella* larva	530 (95%)
	Silk glands of *A. kuehniella* larva	27 (5%)

These two experiments indicate that the contents of the mandibular glands elicit jabbing by the parasites. If a coverslip is exposed to a crowd of host larvae, droplets of mandibular gland secretion are deposited on it (experiment 2). Experiment 4*C* shows that coverslips treated in this way elicit jabbing by the parasites, and that the number of jabbing sessions directed at a coverslip depends on the number of host larvae to which that coverslip was previously exposed. In each of the ten trials of experiment 4*C*, 22 mm square coverslips were put on the floor of four standard boxes containing, respectively, one, five, ten and twenty wandering last-instar larvae

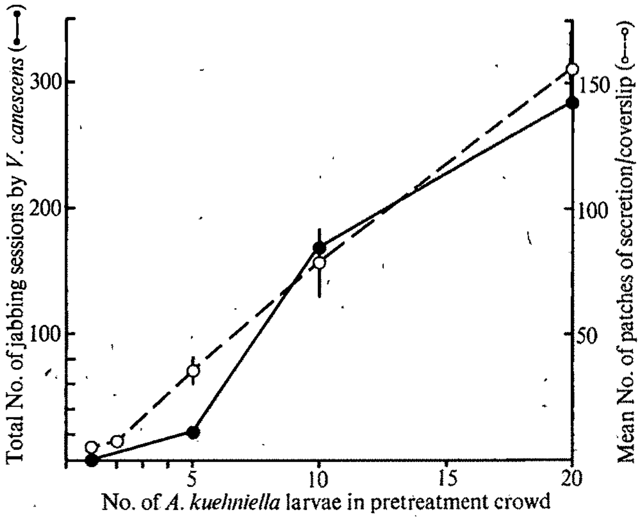

Fig. 4 ●, Effect of pre-treatment of 22 mm square coverslips by exposure for 1 h to larvae of *A. kuehniella* in eliciting jabbing by *V. canescens* (experiment 4*C*). ○, Mean numbers of patches of secretion deposited on 50×22 mm coverslips by larvae of *A. kuehniella* during one hour's pre-treatment (experiment 2). Vertical lines represent twice the standard error.

of *A. kuehniella*. After 1 h at 25° C the four coverslips were removed, arranged in a square and presented simultaneously to between thirty and fifty adult females of *V. canescens* trapped under an inverted glass dish. The number of jabbing sessions directed at each coverslip was recorded during 10 min. The summed results of the ten trials are shown in Fig. 4.

These experiments show that the parasite *V. canescens* responds quantitatively to the secretion of its hosts' mandibular glands, which carries an intraspecific message announcing crowding; the secretion contains material which is, from the parasites' point of view, a kairomone[9]. This case parallels the situation in which the predatory beetle *Thanasimus dubius* (F.) responds to a supposed aggregation pheromone of its prey, the bark beetle *Dendroctonus frontalis* Zimm.[10]. Similar responses of hymenopteran parasites to the mandibular gland secretions of their lepidopteran hosts may occur in other species; *Cardiochiles nigriceps* Viereck, a hymenopteran parasite of *Heliothis virescens* (F.), shows a searching response in the presence of the secretion of the larval mandibular glands of its hosts[11].

The finding of an epideictic pheromone in the secretion of the mandibular glands of *A. kuehniella* may be applicable in the control of lepidopteran pests, especially if the mandibular glands of other species prove to have a similar function[12]. Work is in progress on the chemical characterization of the components of the secretion, making use of the parasites' ovipositional response as a bioassay for the kairomone.

I thank Dr Philip S. Corbet, Professor J. Green, Dr P. A. Lawrence and Professor V. C. Wynne-Edwards for helpful comments.

Presumptive *X* Monosomy in Black Rats from Malaya

DURING a cytogenetic study of the Malayan species of *Rattus* Fischer, black rats, *Rattus rattus diardii* (Jentink), were trapped at Kuala Lumpur, Selangor, and Batu Pahat, Johore, between November 1968 and July 1970. Ninety animals were examined cytologically and seventeen gave chromosome counts that differed from the normal diploid number of 42 (ref. 1). Fourteen had between one and three additional small metacentric chromosomes which were not distinguished from normal members of the complement. Nevertheless, they are assumed to be equivalent to the "inert" supernumerary (or *B*) chromosomes of many invertebrate and plant species. Counts of 41 chromosomes were recorded repeatedly in preparations from four of the rats trapped at Kuala Lumpur. Karyotype analysis indicated that "Robertsonian fusion" between two acrocentric chromosomes had occurred in a male specimen[2]. In the remaining three specimens (all females) an acrocentric chromosome was absent. Observations were made on preparations from bone marrow.

Apparent monosomy was a surprising observation, and so these preparations were re-evaluated. From each animal twenty well spread metaphases were selected at low magnification and counted at high magnification by the sector method (which has the advantage that whatever errors may be made in interpretation the final count recorded is not influenced by prior knowledge of an "expected" number). The results confirmed previous counts. As a further precaution the preparations were sent to another laboratory, where the diploid number was verified to be 41 in all three animals.

Only the two longest and perhaps the shortest of the 11 pairs of acrocentric autosomes can be distinguished individually. The remainder, together with the *X* chromosome, which is also acrocentric, are difficult to separate by size[3]. It is therefore significant that the three animals were all females, and the most reasonable assumption is that all were *X* monosomics. Autopsy of one revealed normal ovaries, uterus and other female reproductive organs, but this is not an inconsistent observation since *XO* female mice are both viable and fertile[4].

The alternative interpretation of autosomal monosomy is highly unlikely. In man several examples of autosomal monosomy have been reported in cultures established from spontaneously aborted foetuses. They are, however, rare in comparison with the numbers of autosomal trisomies identified (theoretically, near equality in numbers is expected in the zygote population). In the one case of a live-born infant reported with non-mosaic monosomy-*G*[5], conservation of a normal or near normal genome by translocation to another site cannot be excluded on the evidence presented. In the mouse, new evidence indicates that autosomal monosomics may develop normally up to the blastocyst stage and even implant, but all die before the tenth day of gestation (personal communication from C. E. Ford).

In the marsupial genera *Isoodon*, *Perameles*, *Echymipera* and *Peroryctes*, loss of one *X* chromosome in females or of the *Y* chromosome in males is a normal event in many somatic tissues though not in the germ cells, which retain the zygotic *XX* and *XY* constitution respectively[6,7]. A single field mouse, *Akodon azarae*, had also been reported to possess an *XO* sex chromosome complement at least in the somatic tissues[8].

Since bone marrow was the only tissue studied in the three *R. rattus* monosomics the possibility has to be borne in mind that the loss of the one chromosome may have been confined to bone marrow and perhaps other somatic tissues. If it were so it would imply a labile system of regulation of sex chromosome loss, operative in a small proportion of animals.

Whatever the explanation, *X* monosomy, an *Isoodon/Perameles*-like system or even autosomal monosomy, the observation is unexpected, leaving many questions to be answered.

I thank Dr C. E. Ford for his interest, and for verifying my chromosome counts.

Frequency of Blood Feeding in the Mosquito *Aedes aegypti*

THE probability that a female mosquito transmits a pathogen from one host to another depends, in part, on the frequency of blood feeding. *Aedes aegypti* (L.) is a vector of several arboviruses, whose feeding frequency has been measured in the laboratory[1–4]. We now present a direct field estimate of this parameter.

Subject to several assumptions[5], the chief population parameters can be estimated by marking, releasing and recapturing individual animals of a population in its natural habitat. It is essential that marked and unmarked individuals have equal probabilities of being captured[6]. An adult female mosquito, however, repeatedly passes through a sequence of behavioural phases such as feeding, resting and oviposition, and no sampling method is known that would confer an equal probability of capture on individuals in these different phases. These disadvantages were largely avoided in our study which also enabled the frequency of blood feeding to be estimated.

The catching area was in the centre of a tree-shaded scrap heap of old motor cars in a suburb of Dar es Salaam (6° 49′ S, 39° 15′ E), on the coast of Tanzania. Large piles of rainwater-filled tyres provided a habitat for a large breeding population of *A. aegypti*. Female mosquitoes which showed attempted biting behaviour were caught by a team of four men during a 5 h period from dawn onwards, on twenty-three consecutive days from June 4, 1970. During the first 11 days (except day 1) captured *A. aegypti* females were checked for marks and given an opportunity to engorge on the experimenters. Fully engorged females, and others bearing a mark, were then lightly etherized and each painted with a single date code mark on the thorax; the technique causes no apparent harm[7,8]. After marking, the females were released at the capture site and most dispersed in the manner typical after feeding. Females not so released were killed. After the eleventh day, captured mosquitoes were merely preserved for checking. All marks were made and interpreted by one of us (G. A. H. McC.).

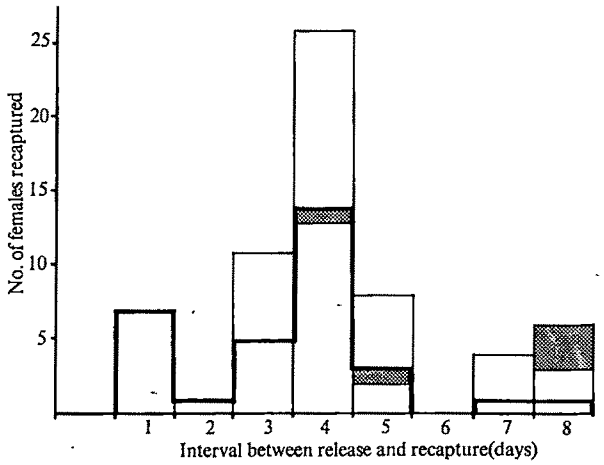

Fig. 1 The results of the mark-release and recapture of females of *Aedes aegypti* during 23 days in Buguruni, Tanzania, expressed as a frequency histogram of the intervals between release and recapture. The area below the heavy line represents females that were released after engorgement and which engorged within 6 h after recapture. The hatched portions of the columns refer to intervals between first release and second recapture for females recaptured twice.

The gross loss on capture of the 579 females caught during the first 11 days was 19.2% and included three which bore a mark from a previous day. Only 1.3% of the 474 females which engorged could not be released after handling. Of 418 singly marked females released, fifty-three were recaptured; fifty of these were released with two marks and, of these, five were recaptured. Because the difference between these recapture rates is insignificant (χ^2 (1)=0.30) data from singly and doubly marked females can be combined. The total of fifty-eight recaptures is 12.4% of the 468 females released. In an open environment this recapture rate is unexpectedly high. In a similar, though longer term, experiment in Thailand on a population of *A. aegypti*, sampled indoors, the recapture rate was only about 4% (ref. 8).

Fig. 1 indicates the frequency distribution of the numbers of females recaptured at various intervals since the date of release. For the five individuals recaptured twice, the intervals between each release and recapture as well as the overall interval are recorded separately. The fifty-eight recaptures therefore provide data for sixty-three release–recapture intervals. After deducting females dying or refusing blood and those caught after day 11, there remain thirty-three unequivocal intervals between engorgements (depicted by the heavy line in Fig. 1). It must be emphasized, however, that some females probably took additional blood meals between the known engorgements at release and recapture.

The striking 4 day modality is clearly an indication of the gonotrophic cycle at the mean air temperature of about 24° C which prevailed during the study. The average intervals between feeding recorded in the laboratory have varied from 3 to 5 days[1–4].

At least half the females in laboratory populations have been reported to feed on the second as well as on the first day of the gonotrophic cycle[2,3]. In the field, several workers[8–10] have discovered that a considerable proportion of biting females were already blood-fed, gravid or partially gravid with sufficient blood to complete ovarian development. It has been suggested[9] that double feeding, in the first gonotrophic cycle, is a response to inadequate larval nutrition. The data reported here, however, not only confirm double feeding in seven individuals recaptured 24 h after release, but, because one of these was recaptured 4 days after initial release and again on day 5, they also imply double feeding in a subsequent gonotrophic cycle.

In Fig. 1 the recaptures at 3, 5 and 7 days can be regarded as deviations from a 4 day mean, with the first day recaptures indicating double feeds in the first gonotrophic cycle only. The results could equally be interpreted, however, as representing an invariate 4 day cycle with a second feed after 1 day in each cycle. With this interpretation the intervals of 3 and 7 days are derived from individuals initially captured as "second feeders" and recaptured taking the first feed of a subsequent cycle. The 5 day intervals are derived from females caught as "first feeders" and recaptured as "second feeders" in the next cycle. The occurrence of a fairly high frequency of double feeding in *A. aegypti* implies that it can be an effective vector of viruses both at lower densities and, if the interpretation of double feeding in later gonotrophic cycles is correct, at lower survival rates than have hitherto been realized.

This study was supported jointly by a US Public Health Service research grant from the Center for Disease Control, Atlanta, Georgia, and the World Health Organization. We thank Dr W. K. Hartberg for his assistance and Mr J. W. Wright and Dr A. W. A. Brown for their interest and support.

Synthetic Mimics of Insect Juvenile Hormone

TERPENE derivatives other than farnesol possess excellent juvenoid activity[1]. We have examined the effects of epoxidized and unepoxidized aromatic ethers of geraniol on yellow mealworm (*Tenebrio molitor*), confused flour beetle (*Tribolium confusum*) and other insects. The compounds can be synthesized easily from commercial materials and are reasonably stable to sunlight and hydrolysis. We have investigated the relationship between their chemical structures and their biological activity in the yellow mealworm[2].

Cecropia hormone†			XV	3.0	

* Effective dose causing abnormal development of 50% of treated pupae.

† Methyl *cis*-10-epoxy-7-ethyl-3,11-dimethyl-*trans,trans*-2,6-tridecadienoate is included for comparison, and was kindly supplied by W. S. Bowers, USDA, Beltsville, Maryland.

Candidate compounds were applied topically in 1 μl. of acetone to the venter of newly formed *Tenebrio molitor* pupea, which were then incubated at 28° C and 75% relative humidity for 7 days. Signs of abnormal development included retention of urogomphi, gin traps, and general appearance of a pupal–adult intermediate[3-5].

Test compounds were synthesized from geranyl bromide by treatment with *m*-chloroperbenzoic acid to form the epoxide, which was then reacted with phenol in 1,2-dimethoxyethane in the presence of powdered potassium hydroxide. Geranyl bromide was used directly in the ether synthesis of the unepoxidized compounds. Structures were confirmed by infrared and mass spectroscopy and by nuclear magnetic resonance.

The activities of fourteen compounds in the *Tenebrio* test are given in Table 1. Seven epoxidized and unepoxidized compounds were compared for morphogenetic activity. The epoxidized forms (VIII) always had a higher order of activity[1], ranging up to eighty times that of the unepoxidized structure (VII). Compound IV, with an ethyl substituent on the phenyl ring, had the greatest activity, and all the compounds were significantly more active than the *Cecropia* hormone (XV), IV being 1,000 times more active than XV.

Compound IV was also tested on a stored product pest, *Tribolium confusum*, to demonstrate the feasibility of pest control by hormones. Twenty adult beetles were placed in glass bottles containing 100 g of flour that had been mixed with compound IV in concentrations varying from 0.01 to 1,000 p.p.m. Untreated flour was fed to control beetles. The results are given in Table 2. Adult development of *Tribolium confusum* was completely arrested by 10 p.p.m. or more and newly formed adults died prematurely even when the compound was present at the lowest test concentration—0.01 p.p.m. Survival of the original twenty adults in the presence of the

Table 2 Effect of Compound IV on *Tribolium confusum* Populations grown in Treated Flour

0=none; + =few; + + =moderate; + + + =many.

highest test concentration (1,000 p.p.m.) eliminated the possibility of direct toxicity of IV to the test insects. The activity of compound IV was superior to MTDD (3,7,11-trimethyl-7,11-dichloro-2-dodecenoate) which arrested development of *T. castaneum* at 100 p.p.m. in the flour diet[6].

These results suggest that stored product pests could be controlled by compounds possessing juvenile hormone activity. They also suggest that compound IV exerts its morphogenetic action through contact and/or ingestion. Compound IV is being tested in other laboratories and already the data indicate morphogenetic and sterilant effects in a variety of insect species including mosquito, tobacco budworm, cotton boll weevil, Indian-meal moth, stable flies, livestock ticks and body lice. Rats, on the other hand, seem to be unaffected by compound IV: when dosed orally with 4,000 mg kg^{-1}, no adverse effects were observed during a 14 day observation period.

Bearing the potential of these chemicals as pest control agents in mind, tests were conducted to obtain information on the influence of environmental factors on their chemical stability. Compound IV was spread in thin films on glass plates to determine the effects of light and air on stability, and known amounts were suspended in tap water to determine hydrolytic effects. At the end of each exposure, compound IV was rinsed off the glass plates with acetone or extracted from water and appropriate aliquots were bioassayed in the *Tenebrio* test. These tests indicated that compound IV is stable to sunlight and air for at least 12 h and that it does not hydrolyse in water in 24 h. These results are encouraging since they indicate that these mimics of juvenile hormones are sufficiently stable to act in a natural environment.

We thank H. Lee, K. Tseng and F. Kamienski for technical assistance.

Natural Selection and the Evolution of Proteins

Jukes and King[1] have attacked my article[2]. They do not quote my published criticism of their arguments[3]. Many of the points are discussed therein, and so a detailed reply is hardly necessary. They do, however, raise one additional matter of importance. They maintain that a selectionist hypothesis would predict radical changes to be favoured over conservative changes. The compelling arguments against this interpretation were clearly stated by Fisher in 1930 (ref. 4). He demonstrated that selection is very unlikely to favour extreme changes.

Deepest Photographic Evidence of an Abyssal Cephalopod

THE bathymetric distribution of marine organisms collected during oceanographic expeditions is often difficult to ascertain because retrieval methods (nets, dredges, and so on) do not always indicate the precise depth at which an organism is entrapped. The level at which organisms dwell can, however, be accurately defined by deep ocean bottom photography.

On a recent Caribbean cruise of USNS Lynch, 340 exposures of the sea floor were obtained at seventeen stations. A modified Alpine multi-exposure camera system was used consisting of two 35 mm cameras mounted on a single frame and actuated by a bottom contact switch. Both cameras utilized the Hopkins water corrected 33 mm *f*/4.5 lenses. An oblique view of the ocean floor was obtained by tilting the lower camera's viewing angle to 40° with respect to the camera frame.

Among the records was the deepest photographic observation yet made of a marine cephalopod[1], a benthic species belonging to the family Cirroteuthidae (Fig. 1). Except for the thin web which unites all arms for part of their length, much of the

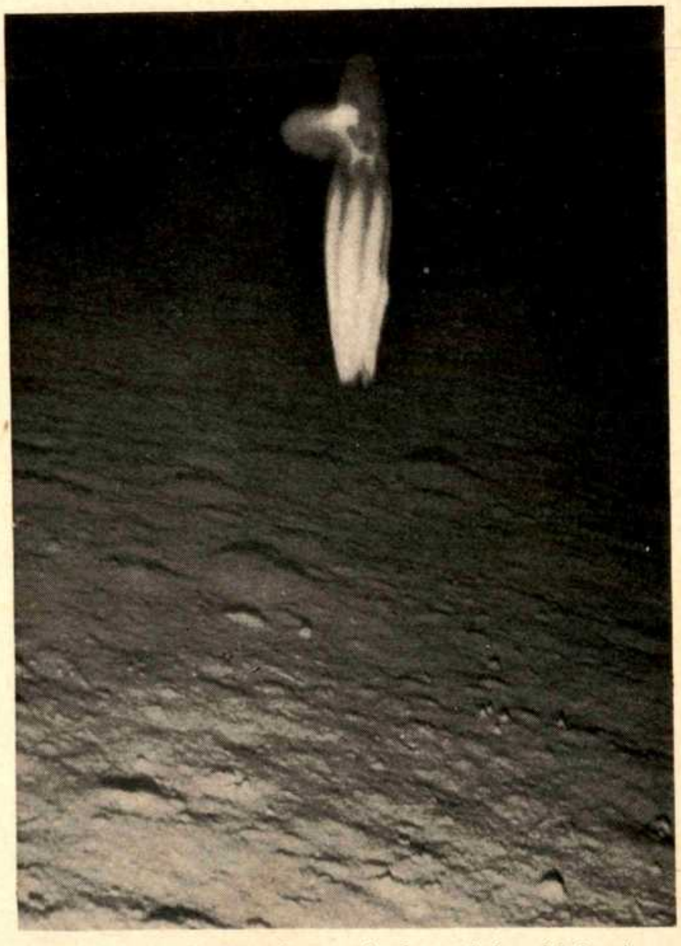

Fig. 1 Ocean bottom photograph of a cephalopod belonging to the family Cirroteuthidae. Taken 325 miles north-east of Barbados in an Abyssal Hill Province at station Lynch 33–14, latitude 17° 28.7′ N, longitude 56° 13′ W, depth 5,145 m on April 12, 1970. The specimen is approximately 1 m above the ocean floor.

external appearance of the octopod is visible. One of the obovate dorsal fins which assist the organism in balance and orientation can be seen, and also the eye, the dark spot located just above the arms. The estimated total length of the specimen is 45 cm.

The specimen may either have entered the camera's field of view from above, or more probably was startled by the camera's intrusion and is seen ascending in an escape reaction. The apparent absence of disturbed sediment would indicate that it was not lying on the sea floor. The sea floor at the camera station is fairly smooth, though numerous small lumps, depressions and oblate mounds are present. A sediment core taken simultaneously with the camera drop reveals the top 20 cm to be a brown slightly calcareous lutite. The potential temperature of the bottom water is 1.4° C (Escowitz and Amos, in preparation).

I thank G. L. Johnson and W. Ruddiman for their help and technical assistance, C. Roper at the Smithsonian Institution for identifying the specimen, and Captain J. Hobbs, the crew af the USNS Lynch and participating Navoceano personnel.

Skeleton of a Late Glacial Elk associated with Barbed Points from Poulton-le-Fylde, Lancashire

THE almost complete skeleton of an elk or moose (*Alces alces* L.) associated with two uniserial barbed points of bone or antler has recently been recovered from one horizon of a series of freshwater deposits revealed by the digging of foundations at High Furlong, Poulton-le-Fylde, Lancashire (NGR SD/3312 3867). An archaeological excavation subsequent to the discovery revealed *in situ* the hind parts of the skeleton and the second barbed point. Stratigraphic data were recorded, and samples were obtained for palaeoecology and dating.

The site lies near the 50′ contour, about 2 miles north-east of Blackpool. Borings were made at regular intervals along an approximately east–west line produced from the face of the cutting in which the skeleton and artefacts were found. These revealed a local depression in the till surface, approximately 40 m from east to west, in which limnic deposits of sands, clays and peats had accumulated. The basin extended in a north–south direction for at least 12 m, but building development in the area made its full extent difficult to determine.

The stratigraphy recorded close to the elk remains was as follows. (Datum was 36 cm below present ground level and 13.47 m above OD.)

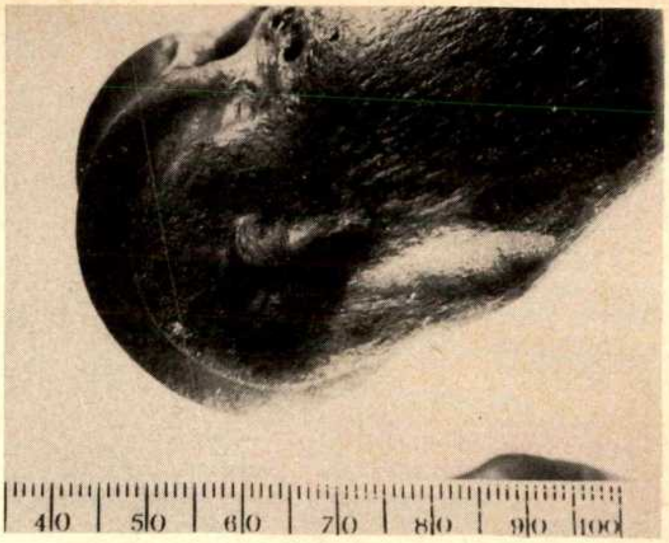

Fig. 1 Left metatarsal showing a lesion caused by one of the barbed points.

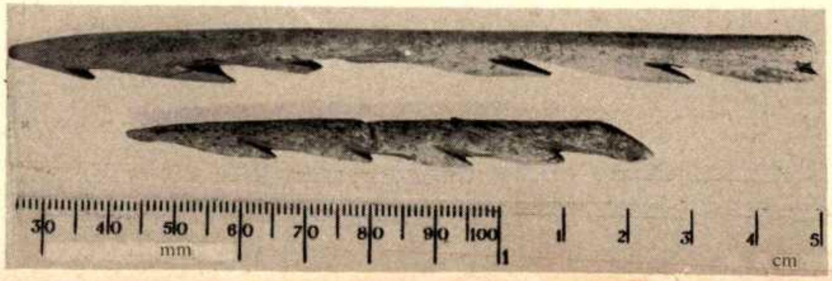
0– 12 cm	Clayey soil
12– 28 cm	Carr peat with *Betula* wood throughout, *Phragmites* leaves and *Potamogeton* fruitstones at base, and *Sphagnum* above 17 cm
28– 31 cm	Grey sandy mud with frost-shattered stones to 3 cm
31– 45 cm	Silty muddy clay
45– 55 cm	Dark grey clay with stones to 5 cm
55– 64 cm	Coarse detritus mud with *Potamogeton* and freshwater bivalve molluscs; elk bones in this horizon
64– 97 cm	Olive-grey calcareous shelly gyttja
97–104 cm	Clay with monocotyledonous fragments
104–123 cm	Red-grey thixotropic clay
123–125 cm	Sandy clay
125–127 cm	Sand with gravel to 5 cm

Nine metres west of this point, close to the centre of sedimentation, the same stratigraphic units attained a total thickness of 270 cm.

The sediments are clearly of freshwater origin. The stratigraphic sequence of clays sandwiching organic gyttja is reminiscent of the familiar "Allerød oscillation" of late Weichselian age noted at other sites in lowland Lancashire[1,2,4] and elsewhere in north-west Europe. Pollen analysis confirms that the deposits from 28 to 104 cm in the profile date from zones I, II and III of the conventional British pollen zone sequence. It is, therefore, unlikely that the age of the elk skeleton is less than 10,800 radiocarbon years BP[3].

The skeleton is that of a male elk, and is almost complete, lacking only the left maxillary teeth, part of the left maxilla, the caudal vertebrae, some carpals and parts of the ribs and

Fig. 2 The barbed points.



sternum. It bears numerous lesions (Fig. 1), and these, together with the presence of two barbed points (Fig. 2) in association with the bones, make it clear that the animal had been attacked by hunters.

The two barbed points, which are very similar, are made from either bone or antler. Both have their basal ends missing; one is 12.3 cm long and the other, found lying in two halves across the base of the left metatarsal of the elk, is 8.0 cm long. Typologically, they are more closely related to the early Mesolithic Maglemosian cultures than to the upper or epi-Palaeolithic Magdelenian or Ahrensburgian. The zone II dating of the horizon in which they were found, however, places them chronologically in the epi-Palaeolithic phase, thus providing a rare link between the cultures of the late Glacial and early Boreal periods.

The original discovery of the skeleton was made by Mr. T. Scholey and Mr. J. Audus. The archaeology is being carried out by J. S. H., and B. J. N. E.; stratigraphic evidence is being studied by B. B., who thanks Professor F. Oldfield for his assistance; and the skeleton is under study by A. J. S. A detailed report is in preparation.

Relationships of *Amphipithecus* and *Oligopithecus*

A RECENT article by Szalay[1] could be taken to be a definitive statement of the relationships of two of the earliest known specimens that can possibly be related to the origin of the catarrhine primates, the group which includes Old World monkeys, apes and men. Each of the fossils concerned—*Amphipithecus* from the late Eocene of Burma and *Oligopithecus* from the Oligocene exposures in the Fayum, Egypt—is known only from a single specimen. A different assessment of their relationships is presented here. Colbert has already shown[2,3] clearly and competently why the teeth and tooth cusps of *Amphipithecus* resemble those of catarrhines. I here outline some observations on how jaws function and why and how the jaw of *Amphipithecus* can be demonstrated to be similar to or different from those of other animals.

There has been much debate about the affinities of *Amphipithecus* as is shown by the following summary: (1) Colbert judged[2] the fragment of this animal—a jaw which contains P_3, P_4, M_1 and roots of P_2 and the canine—to be a probable member of Anthropoidea (the higher Primates) and he emphasized[3] further that this species could be excluded from significant relationship to extinct lemuroids or other lower primates. (2) Piveteau suggested[4] that *Amphipithecus* might either be a relative of South American monkeys (seemingly unaware how surprising its presence in Asia would be), or if not a platyrrhine it was perhaps not a primate at all. (3) Hürzeler found[5] the animal impossible to classify. (4) Remane assessed[6] the animal as standing between lower and higher Primates. (5) von Koenigswald thought[7] it likely to be a lemuroid, but later suggested[8] that it should be cast out of the Primates into the archaic mammalian order Condylarthra (a group of mammals, incidentally, not otherwise found in Burma or elsewhere in Asia). (6) I then repeated that if it was not an anthropoid, it might be an omomyid prosimian and I later stressed[10] again the hominoid similarity. (7) Finally, Szalay has lately argued[1] that *Amphipithecus* is an advanced lemuroid.

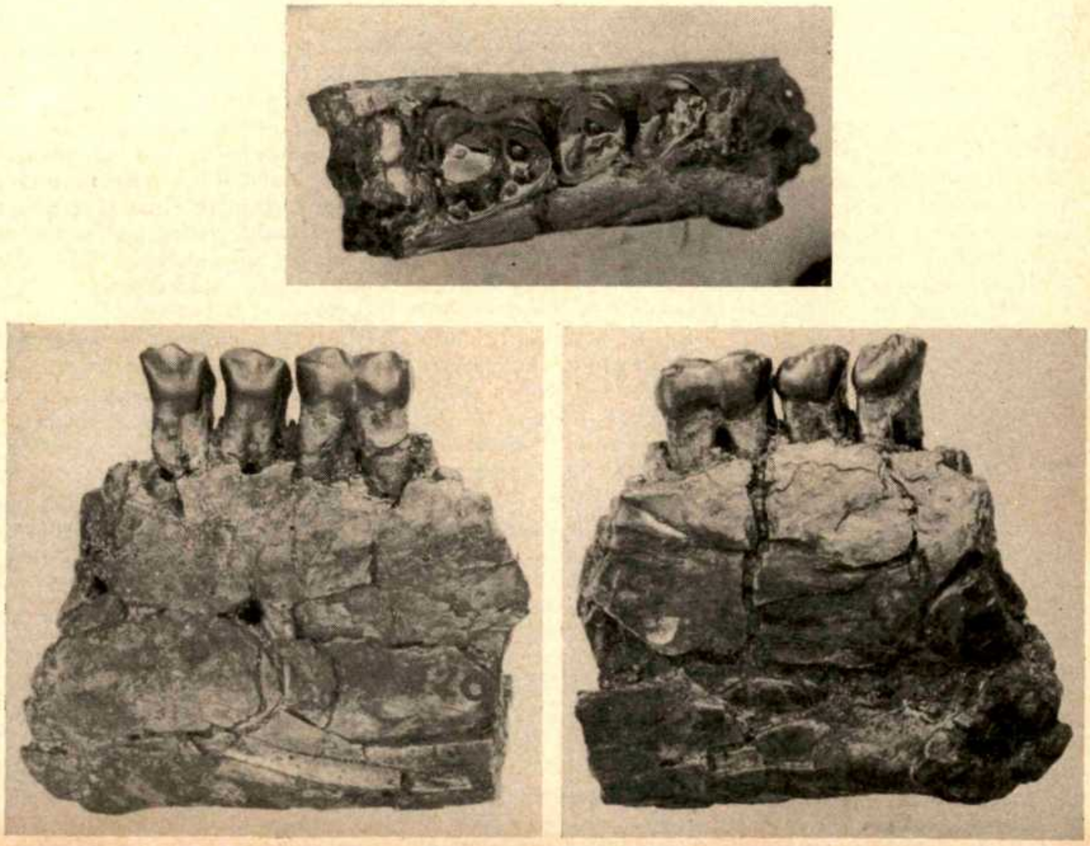

Fig. 1 Crown view (above) and lateral view of the teeth and jaw of *Amphipithecus mogaungensis* from Colbert 1935. The single known specimen is from the late Eocene of Burma.

A solution of the relationships of *Amphipithecus* can be presented in three stages. First, a basic structural and behavioural difference separates all Condylarthra from Primates and equally separates the latter from a large number of later orders presumed to have been derived from the condylarths. Two such orders are Artiodactyla and Perissodactyla but others include most, if not all, of the paenungulate orders. These, in the interpretation of Simpson[11], constitute the orders Pantodonta, Embrithopoda, Dinocerata, Hyracoidea, Sirenia, Pyrotheria and Proboscidea. All the species belonging to these orders are apparently hoofed herbivorous feeders, which cannot convey food to their mouths with their fore or hind limbs. They therefore either have trunks, as in the extant Proboscidea and the extinct Pyrotheria, or lengthened mandibular horizontal rami, usually with elongated diastemata between the cheek teeth and an anterior cropping mechanism which consists either of flared and procumbent incisors in both jaws or of a horny pad opposing the lower incisors. Generalized primates have cheek teeth which are like those of certain artiodactyls and condylarths, but because primates typically use their hands to feed, it is only in Primates and not in Condylarthra or Artiodactyla that the front teeth are not separated from the cheek teeth (the whole tooth row is crowded anteroposteriorly). For the same reason the anterior teeth of certain primates have become relatively small and vertically implanted as seems to be the case in *Amphipithecus*[2,3].

Second, *Amphipithecus* also has an extremely deep mandible compared with the crown height of the cheek teeth preserved; this depth is greater than in almost all mammals with teeth in the same size range, and exceeds even that of the early ape *Aegyptopithecus* (see Fig. 1). Such deep mandibles are characteristic only of certain primates; for example, *Gigantopithecus*[12], many colobines and some platyrrhine monkeys. Great mandibular depth correlates with symphyseal fusion. *Homo* and other hominids also show early symphyseal fusion with small, vertically implanted incisors and have a symphyseal cross-section the long axis of which is oriented almost at right angles to the long axis of the tooth row or horizontal ramus of the mandible. When food gathering shifts to hand or trunk then the importance of incisors in this function decreases. In the case of lemurs and lorises, lower canines and incisors (freed from their food gathering function) have become dental combs for grooming the fur. Elephants have lost opposing front teeth altogether, for food is conveyed to the mouth principally by the trunk. On the other hand, the prosimians generally have anteriorly shallow, separate jaw rami with an unfused anterior symphysis. The few prosimian species that do show symphyseal fusion include the large extinct Pleistocene lemurs of Madagascar, *Archaeolemur* and *Hadropithecus*. These lemurs have long been recognized as having independently converged toward Anthropoidea, and their evolution serves to support the points raised here, for their dental formulae as well as other features prove they cannot be catarrhines although they parallel them. The jaws of prosimians, living or fossil, are never particularly deep. The incisors of such prosimians as the lorises and lemurs project forward and there is little or no development of either the superior or the inferior transverse tori at the back of the symphysis connecting and buttressing the two halves of the lower jaw. This is because these latter structures apparently reach fullest development as they further reinforce the fused symphysis characteristic of higher Primates, including Catarrhini and Platyrrhini. Both these tori are quite large in *Amphipithecus* and it may be that part of the superior transverse torus actually passes the mid-line, which seems likely if, as in all other Tertiary Anthropoidea, the mandibular rami diverged posteriorly. This, together with marked toral development, gives two lines of evidence that there was symphyseal fusion. It should be stressed that there are no primates known below the grade of Anthropoidea (=higher primates), and indeed there are no other mammals which show vertically oriented symphyseal sections, comparatively deep mandibles, orthally directed, crowded, teeth and large tori.

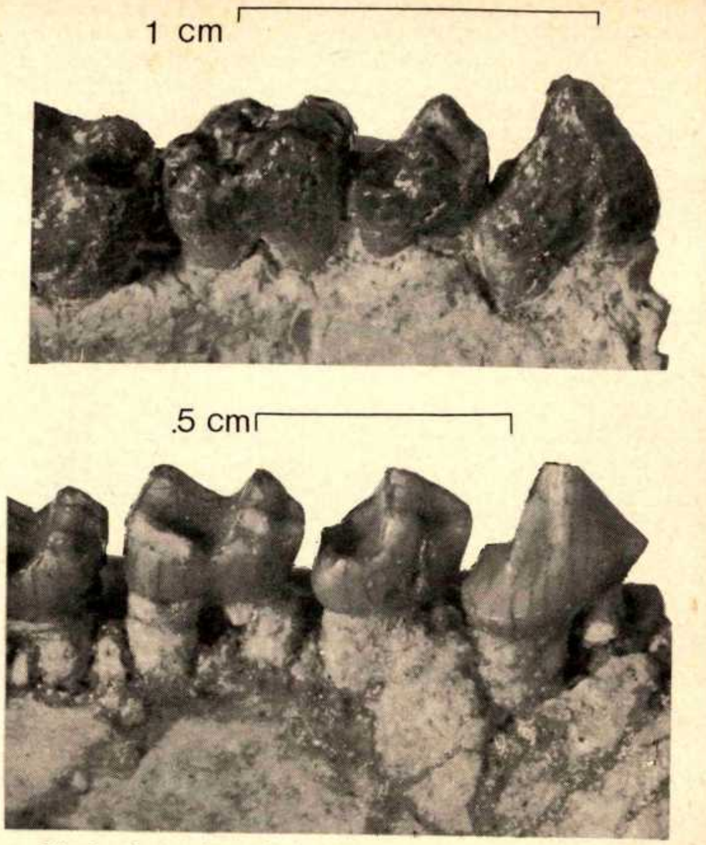

Fig. 2 Comparison of the internal aspect of the premolars and front molars of *Aegyptopithecus zeuxis* (above) and of *Oligopithecus savagei* (below). Both are from the Oligocene deposits of the Fayum badlands, Egypt.

Third, the objection that retention of three premolars is strange for a catarrhine primate has now lost any force it may have had because at least a dozen jaws of the undoubted early catarrhine primates *Apidium* and *Parapithecus* recovered recently by Yale University expeditions under my direction from the Oligocene Fayum of North Africa demonstrate that three premolars are consistently present. Both the Pondaung fauna as well as that of the Fayum contain species of the primitive anthracothere genus *Brachyodus*. This confirms a migration route of some sort between the two areas. Absence of M_1 hypoconulid, if it is indeed entirely absent in *Amphipithecus*[1,2], is not particularly strange, because this animal, even if a member of Anthropoidea, need not be ancestral to any later species retaining this structure. "Hypoconulids" can also arise as neomorphs. Modern cercopithecoids lack M_1 hypoconulids as do many early Primates. Moreover, the hypoconulid is not clearly distinct on M_1 in the archaic catarrhine *Oligopithecus*. This animal will be shown, in what follows, to be a higher primate. Further, Szalay (personal communication) now agrees that *Oligopithecus savagei* is not a prosimian but is a catarrhine.

If *Amphipithecus* is not a member of Anthropoidea then it will have to be considered as belonging to an order of mammals otherwise entirely unknown which might facetiously be called Pseudanthropoidea, or Pseudcatarrhini. *Oligopithecus* must be considered a catarrhine primate because of its complete similarity to Old World Anthropoidea: its jaw is deep, it has only two lower premolars and the anterior of these is elongate and serves as a hone against the back of the upper canine.

The P_2 or P_3 honing function of Anthropoidea is never seen in Prosimii and consequently the full development of this mechanism with highly heteromorphic P_3 and P_4 seen in *Aegyptopithecus* and *Oligopithecus* (Fig. 2) is additional evidence that these Fayum primates were definitely of a higher primate grade. Fig. 3 shows the honing facet of the unique

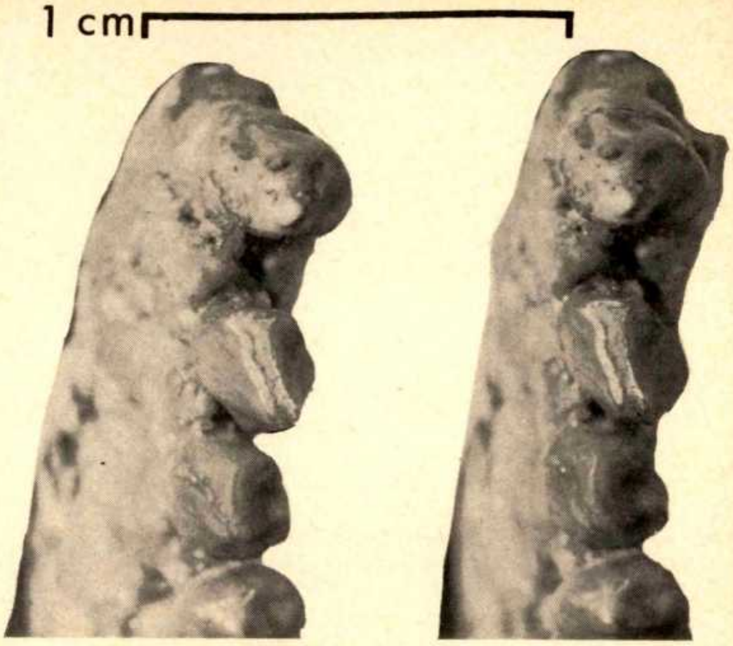

Fig. 3 Stereopair of the anterior part of the left lower jaw of *Oligopithecus savagei* showing the distinct honing facet for the back of the upper canine—a distinctly anthropoid trait.

type mandible of *Oligopithecus savagei*. Clearly *Oligopithecus* is not a prosimian. Its premolars are fully heteromorphic and unlike anything that can be found in any prosimian, living or fossil. The tooth crown surfaces of the new *Aegyptopithecus* mandible have been chemically eroded but this has not obscured its premolar resemblance to *Oligopithecus*. In both P$_3$'s the trigonid is wide open lingually, and the paraconid ridge descends anteriorly just lateral to the mid-line in the long axis of the tooth row. The metaconid ridge of P$_3$ slopes posterolingually in both and ends in the same manner in a slightly enlarged bulb, the presumed homologue of the P$_4$ metaconid. In both there is an internal basal cingulum on P$_3$ but not on P$_4$ or on teeth posterior to it, and in both this cingulum carries a slight swelling just above the space between the large posterior and somewhat smaller anterior root of this tooth. In both species the entoconid and hypoconulid of M$_2$ are closely approximated. One difference (Fig. 2) is that the M$_1$ hypoconid of *Oligopithecus* is higher and less rounded than in *Aegyptopithecus*. The P$_3$ canine hone of *Oligopithecus* (Fig. 3) is well defined and the principal direction of the grinding stroke of the canine is indicated by striations on the wear facet. No prosimian, living or fossil, shows a premolar honing facet of this sort which does, of course, reflect that the functional uses of the front teeth of prosimians are basically different from this.

One or two observations about the unique type specimen of *Oligopithecus* seem worthwhile at this point. This specimen was found by D. E. Savage and was collected by me in December 1961 in quarry E of the lower fossil wood zone of the Jebel el Quatrani Formation, Fayum, Egypt. It was found in a porous lense of gravel-sized matrix. The body of the mandible had been considerably fractured with the result that its parts had expanded and the cracks had been refilled by sand grains. Thus, the teeth, once closed together from back to front, are now separated from each other by gaps. During collection the canine and P$_3$ were unavoidably further tilted apart (see Fig. 2). It has been considered inadvisable to try to move these teeth back into closer approximation because the horizontal body of the mandible is as soft and friable as chalk. As the teeth are now splayed apart, it might be thought that *Oligopithecus* had a P$_2$, but when discovered in place there was no gap between these teeth, and the wear facet for the upper canine seen on P$_3$ (Fig. 3) completely confirms the lack of P$_2$.

In sum, the overall structure of teeth and jaws of *Amphipithecus*, *Aegyptopithecus* and *Oligopithecus* shows numerous anatomical details which only resemble living catarrhine primates. These genera, together with *Proliopithecus*, *Aeolopithecus*, *Apidium* and *Parapithecus*, are therefore the oldest undoubted evidence of Catarrhini. Although *Apidium* and *Parapithecus* of the Fayum do retain three premolars, the specifically catarrhine anatomy of the mandibles of *Oligopithecus* and *Aegyptopithecus* tends to weaken the conjecture that the Fayum primates might have been introduced to Africa by rafting across the South Atlantic Ocean from South America.

Selecting Tests in Diagnostic Keys with Unknown Responses

HERE we outline a method for constructing diagnostic keys from test results, some of which are unknown. The method is then modified to reduce the number of different tests used. Elsewhere[1] we discuss an application to yeasts, in which the primary purpose is not so much the construction of a key, but to find how few out of a set of tests is required to identify all the yeasts.

The average number (m) of steps required to identify a species can be calculated for any key. An obvious objective is to construct the key with smallest m. Other objectives include minimizing the average cost of identification and balancing

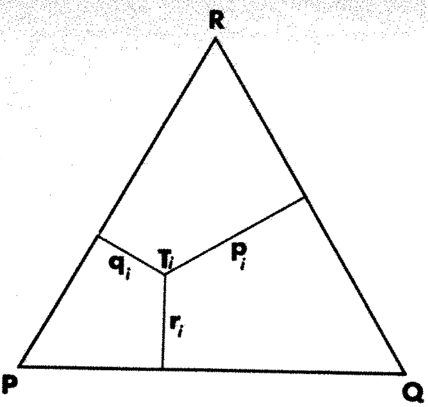

Fig. 1 Representation by areal coordinates of three proportions, $p_i(+)$, $q_i(-)$, and $r_i(?)$, for test T_i.

small m against the number of different tests used in the key. No algorithm seems to be known for minimizing m (apart from the impracticable one of enumerating all possible keys); but the empirical procedures discussed below give approximate solutions.

The results of the tests under discussion are usually presented in an all or none fashion (+ or −). The maximum number of species that can be separated by k binary tests is 2^k and, conversely, n species require at least $\log_2 n$ tests for complete separation. Tests that reduce the number of species to $<2^k$ are not fully efficient[2]. Hence, for any given set of species, in the best possible key (that with minimum m) every test divides its subjects into two groups of equal size. Because this arrangement is usually impracticable, an empirical method for constructing a key is to select tests that most nearly divide the species into equal groups. Several authors[3–6] have discussed this approach to binary tests, but we also consider unknown responses, denoted by "?". These missing values may occur because a test result has not been observed, or is difficult to interpret, or, as in the example discussed by Barnett[1], the test results are variable so that their proper handling would require a probabilistic key, with the additional complications of considering probabilities of misidentification.

When constructing the key, any species with a ? response to a given test used for branching must be included in both + and − branches and hence may appear at a number of ends of the tree. When using the key, any ? response to a test must lead to both + and − branches, so that a specimen may be given several possible identities. At each dichotomy of the key, the test to be selected is that for which the number of + responses most nearly equals the number of − responses, allowing for the ? responses. The selection criterion must depend on the proportions p_i, q_i, and r_i of +, −, and ? responses. The ith test may be represented by a point $T_i(p_i, q_i, r_i)$ in three dimensional space, but because $p_i+q_i+r_i=1$, all points T_i are inside (or on) the equilateral triangle PQR (Fig. 1) cut off by the coordinate axes on the plane $p+q+r=1$. The perpendiculars from T_i on to QR, PR and PQ have lengths $\sqrt{3/2}$ times p_i, q_i and r_i, respectively, and are usually termed areal coordinates. k tests can be represented as k points T_i $(i=1, 2, \ldots, k)$ within the same triangle. If there are no ? responses, the point T_i lies on PQ and the selected test is that nearest O, the mid-point of PQ, that is the test for which $p_i=q_i=\frac{1}{2}$ is most nearly true. When there are ? responses, the most efficient test is here taken to be that for which OT_i is shortest, $OT_i^2=(p_i-\frac{1}{2})^2+(q_i-\frac{1}{2})^2+r_i^2$. On this measure of efficiency, all those tests represented by points on any semicircle (centre O) and within triangle PQR are equally efficient; those within the semicircle are more efficient than those outside it (Fig. 2).

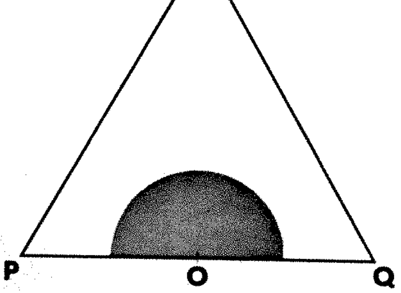

Fig. 2 All tests represented by points on a semicircle, centre O (mid-point of PQ), are equally efficient.

We considered other criteria of test efficiency; for example, the information criterion $I_i=(p_i+r_i)\log(p_i+r_i)+(q_i+r_i)\log(q_i+r_i)$ behaves almost identically to OT_i^2, especially in the region containing efficient tests. The Williams and Lambert association analysis[7] and its extension suggested by Gower[8] have not yet been tried. The criterion of OT_i^2 was chosen for its simplicity, providing an efficient algorithm when included in a computer program; it can also be extended easily to cope with multilevel responses. These virtues are important for computing when the results of many tests have to be examined at every level of the hierarchic key under construction. When several tests are nearly equally efficient, the simplest procedure is to select any one at random, and in practice to select the first encountered.

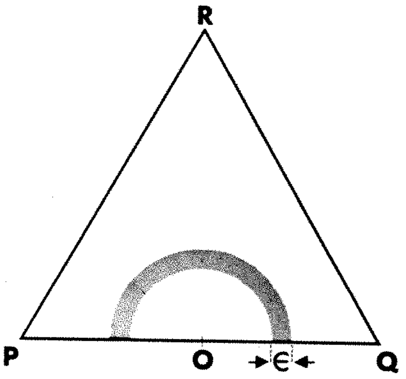

Fig. 3 To increase the chance of finding previously used tests, all points in the annulus, width ε, are taken to represent equally efficient tests.

In botanical identification a step by step method is often used; each test or observation is done consecutively, and the test use at any stage is determined by the outcome of the previous test. Keys constructed by the method described here should then be satisfactory. By contrast, in identifying microorganisms it is usual to do many tests simultaneously before referring to a key. When many hundreds of organisms have to be identified in a year, it may be important to minimize the number of tests that have to be done. A further objective is to partition the key so that the results of the first set of tests determine which tests are in the second set; in this way the number of tests for identification may be greatly decreased.

To minimize the number of tests used, the criterion described was modified to increase the chance of finding a test that occurs elsewhere on a different branch of the key. This was done by regarding as equally efficient all tests within an annular region of width given by the difference between the radii OT and $OT+\varepsilon$ (Fig. 3). Several values of ε(0, 0.05, 0.1, 0.3, 0.5) were tried for sixty-eight species of fruit yeasts; m ranged from 6.61–6.84, and the number of different tests from twenty-four to twenty-five. Here, at least, little was gained by varying ε. This was mainly because certain tests were essential for separating pairs of similar species; although these tests were not needed in the earlier levels of the key, they had to be included later. When selecting one of several tests in the ε-annulus, two strategies were tried. The selected test was either (i) that used most often before, or if none, the most efficient test, or (ii) the most efficient test of those used before, irrespective of how often used.

To obtain partitioned keys with this program, a modification of the ε-process might be used, although it was not tried. In this method, the highest level of the key at which each test has been used is recorded, and the best test used previously at the highest level is selected from the ε-annulus. The computer program constructs the key by completing the branches from left to right. Alternatively, the levels from top to bottom could be completed; this would be more suitable when trying to minimize the number of tests used in different partitions of the key, but it is less efficient computationally. This strategy, and that of building the key from bottom to top, are being investigated.

Two or more tests used simultaneously may give more help in identification than both used separately; in this context Pankhurst[4] has a simple but effective formula for + and − responses only. Following the success of applying the present work, as described in the companion paper[1], we are investigating the handling of ? responses when considering two or more tests simultaneously, and also studying the effects on the calculations of permuting the order of the tests.

Electron Microscope and Optical Diffraction Studies on Isolated Cell Walls from *Chlamydomonas*

THERE are few high resolution electron microscope studies specifically concerned with the architecture of the cell walls of the green alga *Chlamydomonas*. Sager and Palade[1] state that the wall of *C. reinhardi* is a multilayered structure about 40.0 nm thick and that the structure is consistent with the cellulose wall described from light microscope observations. The description of the wall given by Walne[2,3] and by Cavalier-Smith[4] is essentially similar to that given by Sager and Palade. Barnett and Preston[5] using the freeze etching technique reported the presence of oriented microfibrils in the cell walls. The regular features were interpreted as being cellulose which was thought to be synthesized by small granules associated with the surface of the plasmalemma. In the related species *C. moewusii* the wall had a regular periodicity of 23.3 nm, and again the striations were interpreted[6] as being cellulose fibrils, but it was noted that the spacings were smaller than those observed in other structures containing cellulose fibrils[7].

The preliminary findings we wish to report concern the application of various chemical and physical methods to the isolation and characterization of the cell wall material isolated from *C. reinhardi* with particular reference to the ultrastructural features and their analysis by optical diffraction[8,9]. In addition to the wild type strain we have examined two of a series of mutant forms we have isolated[10], which show defects in various aspects of cell wall biogenesis. Cell preparations were obtained from liquid cultures and concentrated by low speed centrifugation. Pellets were placed in a Mickle shaker and disintegrated in the presence of glass beads. Fractions containing cell wall material were obtained by differential centrifugation as applied to the separation of bacterial cell walls[11]. Centrifuged pellets containing walls were monitored for purity by examination in the phase contrast microscope and by electron microscopy. The purity and concentration of a typical cell wall fraction are illustrated in Fig. 1. Examination of shadowed specimens in the electron microscope revealed typical cell walls of the type shown in Fig. 2. The striations observed at low magnification were essentially similar to those reported by Lewin *et al.*[6] but the spacing of 13.5 nm determined from Fourier transforms was considerably smaller (Fig. 2 inset).

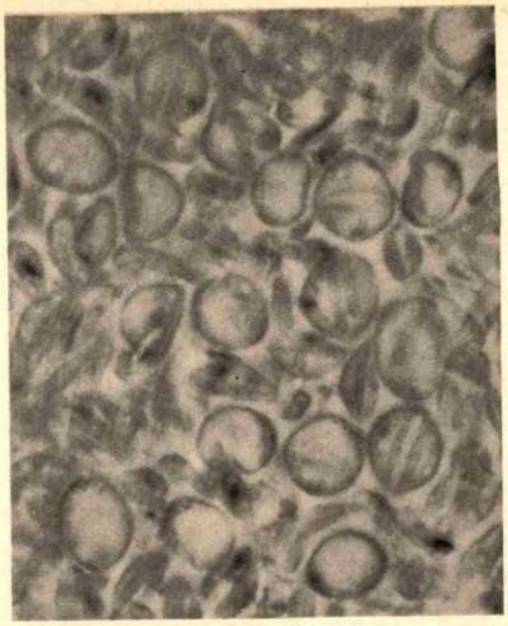

Fig. 1 Phase contrast micrograph of isolated cell wall fraction.

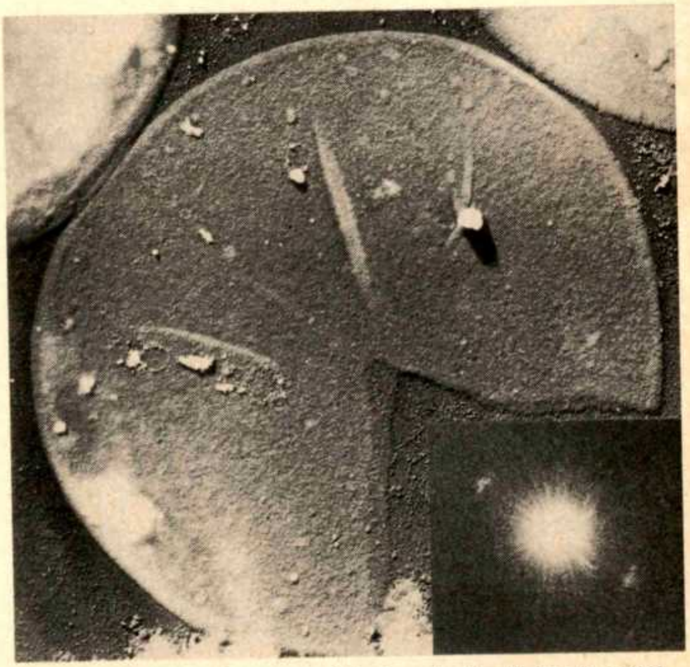

Fig. 2 Electron micrograph of shadowed cell wall. Inset: optical transform obtained from a shadowed cell wall, indicating regular periodicity of 13.5 nm.

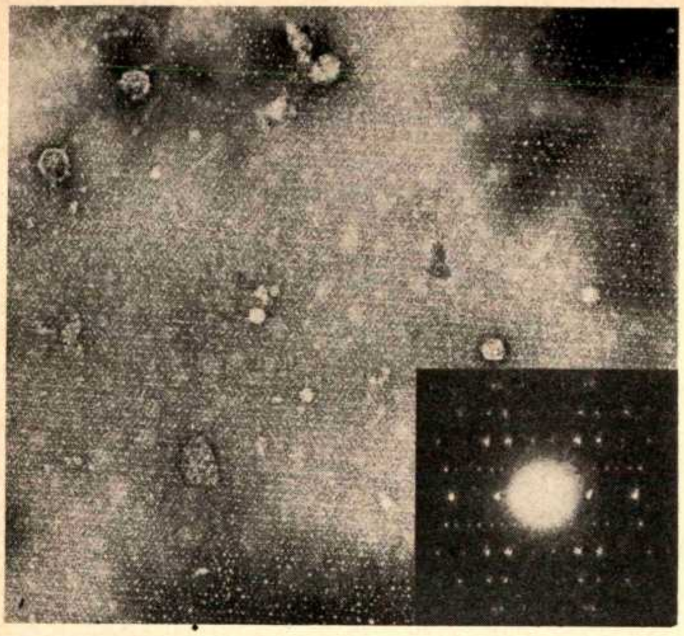

Fig. 3 Electron micrograph of negatively stained preparation of cell wall showing a regular lattice structure. Inset: optical transform from the same area.

Studies of thin sections of intact cells and cell wall fractions prepared by a variety of fixation and staining procedures showed the wall to have a structure similar to that described by the workers mentioned earlier. It was constructed of several electron dense layers arranged approximately parallel to each other. The layered region was about 19.0 nm across (after osmic glutaraldehyde fixation). In addition to the electron dense layered regions, the inner and outer surfaces of the cell wall when seen in thin sections showed different morphological features. At the inner surface a diffuse region was observed and appeared to consist of small particulate material, whereas the outer surface suggested the presence of long filamentous structures of about 3.4 nm in diameter being released from the wall.

After preparation of the wild type cell wall material in the presence of 2% ammonium molybdate or 2% potassium phosphotungstate (*p*H 6.8), and examination at high instrumental magnifications in the electron microscope, micrographs were recorded showing a well defined lattice pattern as illustrated in Fig. 3. Examinations of the micrographs in an optical diffractometer indicated that the cell wall was constructed of a complex lattice as shown in the inset of Fig. 3. The lattice structures appear to form layers in the cell wall and are positioned at preferred angles relative to each other. In the case of the pattern illustrated in Figs. 3 and 4, it is possible to interpret the structure as being two basic layers orientated at about 20°. The values relating to the layer lines from the crossed lattice are indicated in the diagram of Fig. 3 which is from the Fourier transform of the inset of Fig. 3. High resolution electron micrographs suggest that the diameter of the fibrils comprising the lattice determined from negatively stained specimens is about 3.8 nm (fifty measurements). The two mutants examined, CW2 and CW20, are defective in that the former cannot attach the wall to the plasma membrane and sheds it into the medium, and the latter, though having an attached wall, has no structural rigidity provided by its wall. Examination of the isolated walls from these mutants, however, revealed that the structural features and the spacings of the lattice were identical with those seen in the wild type wall.

Previous observations[12] relating to the composition of *C. reinhardi* have suggested that about 50% protein dry weight is present in the cell wall. Our own preliminary analysis of the amino-acid composition of the isolated cell wall fraction points to a value of about 35% protein dry weight, but a more detailed analysis is in progress and will be reported later.

We have carried out a number of experiments on the treatment of isolated cell walls of *C. reinhardi* with trypsin prepared according to the methods of Kosta and Carpenter[13]. Those treated with trypsin for 2 h at 37° C no longer retain the regular lattice structure as determined by electron microscopy. Following prolonged treatment with the enzyme they become disorganized and retain only a vague resemblance to their original shape and size. Treating the walls with 10 M KOH incubated for 2 h at 50° C also resulted in the loss of all morphological features corresponding to the original lattice and overall structure detectable by light and electron microscopy. Moreover, there was no evidence to show the presence of fibrils which would correspond to cellulose microfibrils in either the trypsin digests or after KOH extraction. In addition to treatment with trypsin and KOH extraction, several experiments were carried out in an attempt to remove the lattice structure with cellulases. Treatment with cellulase enzyme failed to remove or change the lattice material.

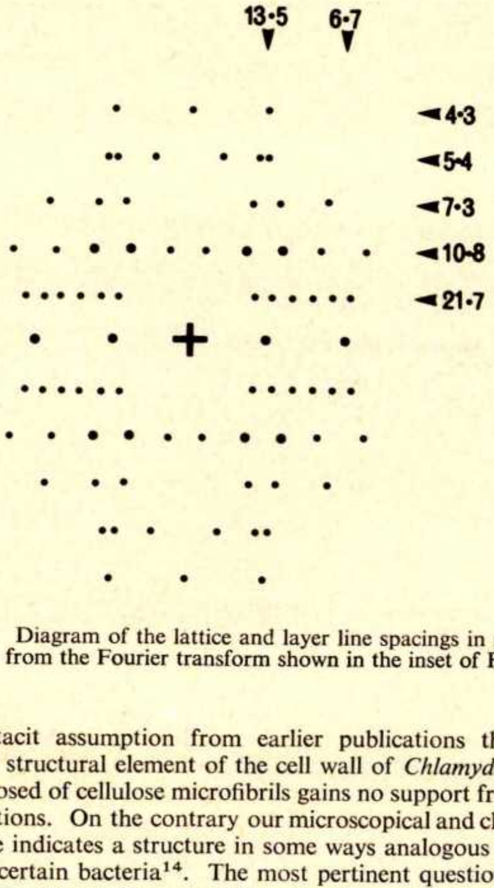

Fig. 4 Diagram of the lattice and layer line spacings in nanometres from the Fourier transform shown in the inset of Fig. 3.

The tacit assumption from earlier publications that the primary structural element of the cell wall of *Chlamydomonas* is composed of cellulose microfibrils gains no support from our observations. On the contrary our microscopical and chemical evidence indicates a structure in some ways analogous to that seen in certain bacteria[14]. The most pertinent question to be answered relates to the assembly mechanism which gives rise to the regular lattice structure depicted in Fig. 3, and in this context the eighty mutant forms we now have available which are defective in various aspects of cell wall biogenesis will be particularly useful. Our most recent studies suggest that the basic structural units for the wall are assembled from individual layers at the inner wall surface. This material, located between the plasmalemma and the cell wall, seems to be morphologically different from the slender strands which can be seen being released at the outer cell wall surface. Our tentative interpretation of these observations is that while assembly of units occurs at the inner wall surface, at the outer region of the cell wall, layers are being shed into the surrounding medium as long slender flexuous filaments with dimensions close to the structures forming the lattice pattern described above.

We thank Mr M. Rees for carrying out the preliminary amino-acid analysis, Mr G. J. Hills for assistance in optical diffractometry, and Mr S. Frey for photographic assistance.

Wolffia arrhiza as a Possible Source of Inexpensive Protein

THE development of new foods is vital to the needs of the rapidly expanding population in Asia. But apart from the necessity of being competitive in market price, they must be acceptable to the human palate, a requirement that has often frustrated attempts to introduce new foods. In this light, the improvement of production and processing of a commodity which is currently marketed for direct human consumption but on a small and inefficient scale has several advantages. Such a commodity is the aquatic plant, *Wolffia arrhiza* Wimm., Lemnaceae, known to have been used as a vegetable by the Burmese, Laotians and the people of northern Thailand for many generations. The local Thai name for the plant, "khai-nam", may be literally translated as eggs of the water and suggests the oval shape of the plant (length 1.5 mm, width 1.0 mm). Khai-nam is generally regarded as a poor people's food and has attracted little attention as a potentially significant source of human food. The species also occurs in India[1], but no report has been made pertaining to its application as a food source in that country.

We have observed the native methods of cultivating *Wolffia arrhiza* and have analysed samples. Small scale cultivation by rain-fed open ponding methods is carried out by villagers living near provincial urban centres in northern Thailand. The *p*H of the water in all the ponds visited (more than 100) was between 6.5 and 7.0, and most were small (60–100 m²) and shaded by bamboo groves. No chemical fertilizers or manures were added. In controlled laboratory conditions, *Wolffia* has been found to reproduce vegetatively by budding and to have a generation time of approximately 4 days[2,3]. But natural conditions with higher light intensities and temperatures seem to be more conducive to growth. In practice, the plants are harvested at intervals of 3 to 4 days during which period the relatively small number of plants remaining from the previous harvest multiply into a thick mass of yellowish-green plants at the water's surface indicating that several generations may have arisen within 4 days. Longer time intervals between harvests invariably lead to lower yields and a product containing a significant portion of dead brownish individual plants which, being unattractive, fetch a low market price. A record of harvesting over a period of 4 months from randomly chosen ponds revealed that the average yield of fresh marketable plants (collectively containing an average of 4% dry matter) is 0.68 kg/m²/week.

In the climatic conditions of the town of Chiengmai in northern Thailand (lat. 19° N, long. 99° E), *Wolffia arrhiza* remains in its edible vegetative form between November and July. The inedible sexually reproducing form prevails between August and October. On the basis of a 9 month period of productivity the calculated annual yield is 265 tons/ha fresh weight or 10.5 tons/ha dry weight. The chemical composition and annual areal yields of *Wolffia* are listed and compared with conventional crop yields in Table 1.

Table 1 Proximate Analysis and Yields of *Wolffia arrhiza* in Comparison with Conventional Crops

Component	*Wolffia*, dry weight %	Average yield (kg/ha/year)				
		Wolffia	Soybean	Groundnut	Rice	Corn
Protein	19.8	2,080	303	229	71	179
Carbohydrate	43.6	4,589	255	164	849	1,451
Fats	5.0	533	158	397	4	87
Fibre	13.3	1,398	44	21	3	40
Ash	18.3	1,928	41	20	5	24
Water	0	0	89	51	124	238
Total	100.0	10,528	890	882	932	1,772

The protein nitrogen was determined by the Kjeldahl method. Fats were extracted by the Soxhlet technique using dichloromethane. The rice was converted from paddy to dehusked rice (ratio 0.66) and groundnut was converted from unshelled to shelled groundnut (ratio 0.60). We determined the composition of *Wolffia*; those of crops were computed from US Department of Agriculture data[4]. Other data on conventional crops were obtained from the Food and Agriculture Organization[5].

In terms of annual yield, *Wolffia* produces more dry matter than the traditional crops grown in Thailand. The protein yield of *Wolffia* is several times greater than those of the local crops. So far, no attempts have been made to increase yields by improving growth conditions but studies will be undertaken to determine the effects of supplemental nutrients, controlled incident solar radiation, harvesting periodicity and mixing in batch and continuous outdoor conditions. Dependent variables will include growth rates, areal yields, proximate analyses of the product, water requirements, nutritional value, production economics and market potential. The research will be directed towards establishing optimum production conditions giving greater yields at lower costs. The naturally occurring species, *Wolffia arrhiza*, will be studied first because of its proven market and nutritional acceptability.

Effect of Purified Luteinizing Hormone Releasing Factor on Normal and Hypogonadotrophic Anosmic Men

THE occurrence of familial and nonfamilial cases of hypogonadotrophic hypogonadism and hyposmia or anosmia (Kallman's syndrome) has been well documented[1,2]. Because the disease has been found only in humans, little is known about the site of the gonadotrophic lesion. Pathological examination of the pituitary glands of these patients has not revealed any abnormality[3]. No estimates of pituitary gonadotrophin content in patients with hypogonadotrophic hypogonadism are available, although patients who have normal amounts of circulating follicle stimulating hormone but who lack luteinizing hormone (LH)—the so-called "fertile eunuch syndrome"—have been described. In contradistinction to the Kallman syndrome, these (potentially) fertile patients have a normal sense of smell and testicular development with varying degrees of spermatogenesis[4]. Injections of gonadotrophic substances cause an appropriate gonadal response in patients with Kallman's syndrome[5] and the lesion is considered to be central in origin[6]. Attempts to stimulate the release of gonadotrophin in these patients by the use of the antioestrogen clomiphene citrate have been unsuccessful[7].

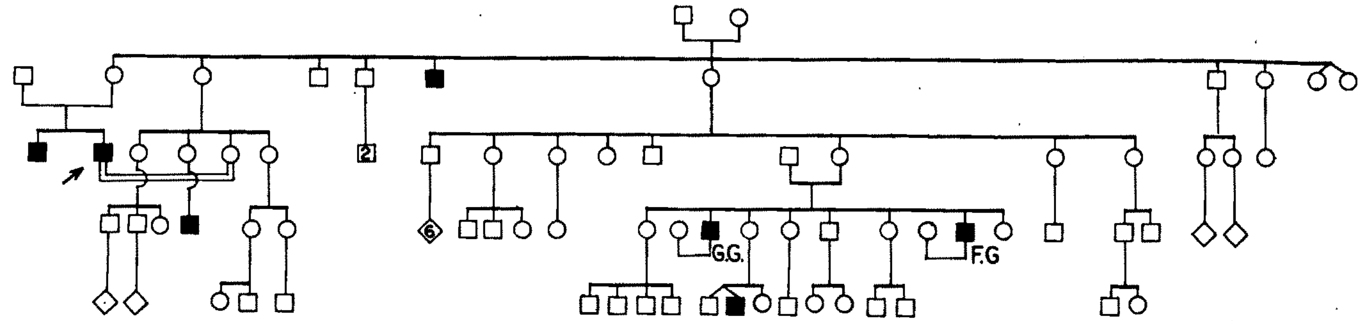

Fig. 1 Pedigree of the hypogonadotrophic subjects. Closed squares denote males with hypogonadotrophic hypogonadism and anosmia.

We have used purified luteinizing hormone releasing factor (LRF) to study these individuals. Two brothers aged 28 and 30 with hypogonadotrophic hypogonadism and anosmia are part of a kinship demonstrating this syndrome (Fig. 1). F. G. (age 28) had taken methyl testosterone (25 mg twice a day) with both subjective and objective signs of androgenization until 2 weeks before receiving LRF. G. G. (age 30) had taken 10 mg of methyl testosterone daily without any response. G. G. was pretreated with clomiphene citrate (300 mg daily for 5 days followed by 5 days of no treatment) before receiving LRF. Both patients were given 300 median eminence extract equivalents (MEE) of purified ovine LRF in physiological saline solution (stage three[8] prepared by Dr H. Gregory) by intravenous drip over a period of 3 and 6 min respectively without untoward effects after an initial episode of flushing. A normal male control (M. B., age 32) was given 100 MEE of ovine LRF by intravenous drip over a period of 7 min. All three subjects had an intravenous physiological saline drip running for 30 min before injection of LRF. The subjects were unaware of the time that the LRF infusion began. The results of this treatment were measured by radioimmunoassay of plasma LH[9] and are shown in Fig. 2. As expected, in the control male there was an abrupt increase in plasma LH with a characteristic time course including a peak 35 min after infusion began. The two hypogonadotrophic brothers had very low levels of plasma LH which at no time during treatment reached the lower limits of normal for males although they had received an LRF dose three times that given the normal male. Yet both had a rise of plasma LH from control values (1.6±0.1 mIU/ml. (F. G.); 1.8±0.15 mIU/ml. (G. G.)) to peaks at 2.7 and 3.5 mIU/ml. respectively 10 min after infusion began. Although the responses were small, they are within the sensitivity of the method and we believe that they represent a real response. At no time during the preceding 6 months did repeated control levels of plasma LH exceed 2.0 mIU/ml. in the two experimental subjects or in two other affected members of this kinship who had not received testosterone. There was no immunological LH activity in the LRF preparation when it was tested in assays which measure sheep or human LH. The possibility of a non-specific response is ruled out by the lack of response to the control infusion and the characteristic timing of the responses to the LRF infusion[10]. The lack of an effect of stress on LH levels in the male has been reported[9]. All three subjects showed what may have been a slight secondary peak in plasma LH 2 h after infusion with LRF. Dosing with clomiphene citrate (300 mg/day) did not have a measurable effect on plasma LH in subject G. G. Nor can we see any potentiating or other effect of the clomiphene pretreatment of the response of G. G. compared with F. G.

The minimal responses in affected patients could reflect a lesion in the pituitary gland or be the result of chronic depriva-

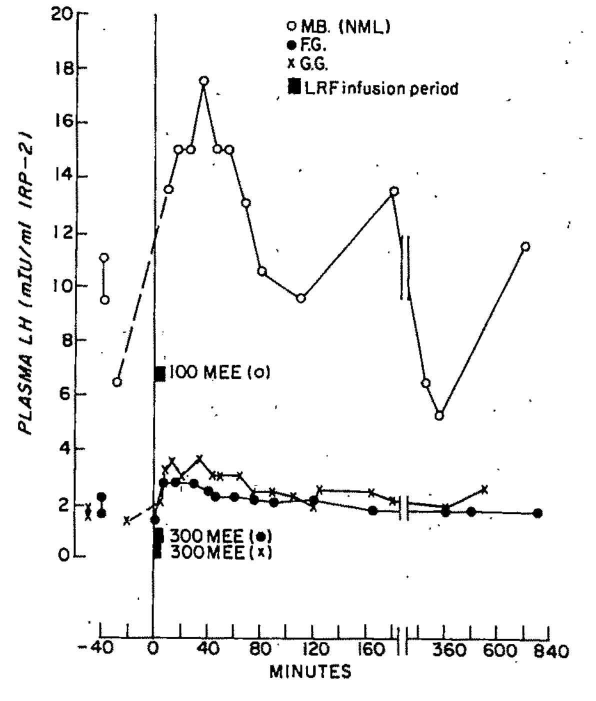

Fig. 2 Plasma LH during control periods and after LRF infusion. ○, M. B. (NML); ●, F. G.; ×, G. G.; ■, LRF infusion period.

tion of releasing factors secondary to a central nervous system disorder. In this regard studies utilizing more prolonged dosage or measurement of pituitary gonadotrophic content in these patients will be of interest.

We thank Dr C. Alvin Paulsen for reagents and Mr M. C. Sood for technical assistance. Part of this work was supported by a grant from the Medical Research Council and a special research fellowship, National Institute of Child Health and Human Development, US Public Health Service (to F. N.).

Haemoglobin Type and Fertility of Merino Ewes grazing Oestrogenic (Yarloop Clover) Pastures

Clover infertility disease in sheep is attributed to the high concentrations of oestrogenic substances found in certain legumes such as subterranean clover, variety Yarloop[1]. Reduction in flock fertility can be as high as 75% with additional losses of lambing ewes due to dystocia[2,3]. Where large areas of these clovers are grown, as in western and southern Australia, the economic loss is considerable. Significant progress has been made in selecting clover varieties which have a low oestrogen content[4] but replacement of established oestrogenic species has had limited success and the cost of renovation is often prohibitively high. We wish to report some observations which suggest that it may be possible to select and breed animals likely to be resistant to clover infertility disease using existing flocks classified on the basis of their haemoglobin (Hb) type.

The reproductive performance of fifty South Australian Merino ewes (Koonoona strain) grazing Yarloop dominant pastures was compared with that of fifty similar ewes grazing neighbouring rye grass pastures essentially free of Yarloop clover. Both groups were mated for the first time at 1.5 yr of age in February 1969 and again in February 1970. Mating and lambing performance was recorded and surviving ewes were Hb typed[5] in November 1970.

The data from 1969 and 1970 showed similar trends and are presented as combined totals in Table 1. The small number of HbAA type ewes were combined with the HbAB types to allow statistical comparison (χ^2) of fertility between Hb types within pasture types. Fertility of ewes grazing Yarloop (53.0%) was significantly ($P<0.001$) lower than that of ewes on grass pasture (83.1%). But on the Yarloop pasture, the HbBB types were significantly ($P<0.01$) less fertile than HbAA+AB types suggesting that the HbA gene is associated with a fertility advantage on oestrogenic pastures which is not apparent on non-oestrogenic pastures.

Table 1 Fertility and Haemoglobin Type of Ewes grazing Yarloop versus Grass Pastures for 1969 and 1970

	Hb type				
	AA	AB	BB	Total	χ^2 value of difference between Hb types (AA+AB)−(BB)
Yarloop pasture					
No. of ewes mated 1969	4	23	17		
1970	4	22	13		
Total	8	45	30	83	
No. of fertile matings	8	26	10	44	
% of fertile matings	100.0	57.8	33.3	53.0	7.55†
Grass pasture					
No. of ewes mated 1969	6	20	21		
1970	4	17	21		
Total	10	37	42	89	
No. of fertile matings	10	30	34	74	
% of fertile matings	100.0	81.1	80.9	83.1	0.32 (n.s.)
χ^2 values of fertility difference between pastures within Hb types	5.22*		15.35‡	18.17‡	

n.s., $P>0.05$; * $P<0.05$; † $P<0.01$; ‡ $P<0.001$.

The possibility of an association between Hb type and reproductive performance in sheep was first reported by Evans and Turner[6], who investigated Peppin Merino flocks in the Cunnamulla district and Deniliquin district of eastern Australia and found that ewes with Hb type BB and HbAB were slightly more fertile than HbAA ewes. In contrast, Obst[7,8] has found in experiments at Parndana Research Station, Kangaroo Island, using south Australian Merino (Bungaree strain) sheep that the HbAA ewes produced more lambs and that these lambs survived better than lambs from ewes of the HbAB or HbBB type.

In the light of this evidence, differences between the reports could be resolved by taking into account the previously unsuspected susceptibility of HbBB ewes to clover disease. Clover disease is a continuing problem on Kangaroo Island and it is therefore significant that Obst and Evans[8] reported that the superior reproductive performance of the HbAA ewes was best expressed during wet lambing seasons when Yarloop clover tends to dominate in mixed pastures at Parndana. The nature of the relationship between Hb type and resistance or susceptibility to clover disease remains to be determined. Some ewes are resistant to clover disease, for even in severe outbreaks they maintain good reproductive performance in spite of the measured high oestrogen content of the pasture[9].

It has been suggested that the oestrogenic activity of the plant isoflavones is due to their metabolic derivatives[10,11] and individual differences in these transformations might be expected. Differences could exist in the ability of individual animals to metabolize and excrete active substances. Alternatively, the Hb type itself may confer some yet unknown physiological advantage. HbA is known, for example, to have a greater affinity for oxygen than HbB with a different oxygen dissociation curve[12]. Conceivably, this may have implications for gamete, embryo or foetal survival.

Haemoglobin type in sheep is controlled by a pair of alleles at a single locus[5] and therefore the HbAA gene frequency of any flock can be readily increased by mating with HbAA type rams. If the relationship of Hb type to clover disease susceptibility is confirmed in Merino and other breeds by more extensive trials, now in progress, Hb type selection could provide a practical basis for low cost management of this disease.

Effects of *l*-Δ^1-Tetrahydrocannabinol on Temporally Spaced Responding and Discriminated Sidman Avoidance Behaviour in Rats

Several investigators have attempted to find a safe but reliable means of determining whether a new drug will produce hallucinations in man[1-4]. Smythies *et al.* have found that rats show a characteristic "hallucinogenic profile" on various standard behavioural tasks. We ran rats on two of these tasks—responding on a differential reinforcement of low rate (DRL) schedule and discriminated Sidman avoidance—after administration of *l*-Δ^1-tetrahydrocannabinol (THC), a known hallucinogen for man[5-7]. We hoped to find out whether the rats would display the hallucinogenic behavioural profile; and by using the same dose range for each task, to find the dose-effect relationship.

The THC came from a single sample and was stored dry in a sealed container under nitrogen. Analysis by gas liquid chromatography (3% OV-17 on Gas Chrom Q, glass column 5×1/8 feet at 250° C) yielded 95% pure THC after 1 year of storage. The vehicle consisted of 50 µl. of double-distilled ethanol plus 950 µl. of 1% 'Tween 80' in steroid suspending medium. The THC was added to the vehicle immediately before use.

A rat on a DRL schedule receives reinforcement (usually food or water) only if it pauses for a predetermined length of time (say 10 s) since its last response. Responses which occur before the end of the interval reinstate the entire interval and postpone reinforcement, so that the schedule promotes long interresponse times. Smythies *et al.*[4,8] have reported that when rats have been trained on DRL 15 (s) their lever-pressing behaviour is susceptible to disruption by the administration of hallucinogenic drugs. Specifically, a relatively small dose of mescaline HCl (12.5 mg/kg) has "... an all or none inhibitory effect on positively reinforced behaviour. At the onset of action the animal stops pressing the lever quite suddenly and restarts abruptly sometime later"[4]. To the best of our knowledge, there have been no reports of other drugs producing this particular pattern of behaviour. Sample cumulative records obtained from our rats under 12.5 mg/kg mescaline on DRL 10 are shown in Fig. 1, and agree with those of Smythies *et al.* in spite of minor differences in procedure. The cumulative records clearly show a cycle of normal responding, complete cessation, and sudden return to accurate temporal responding. Our object was to find out if THC would produce the typical hallucinogenic (mescaline) profile.

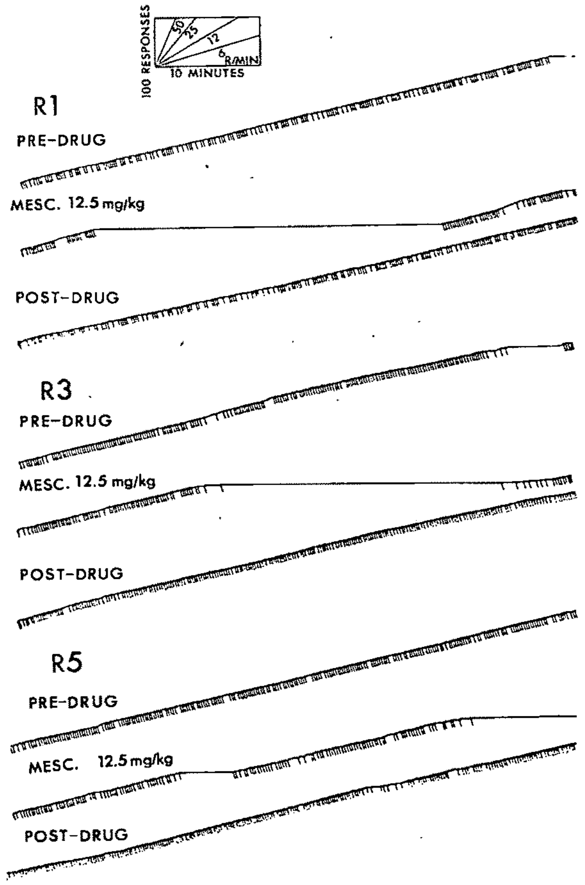

Fig. 1 Cumulative response records obtained from rats R1, R3, and R5 under 12.5 mg/kg of mescaline. Slope of line is a direct function of rate of responding. Reinforcements are indicated by downward pips. Records obtained on the day before drug (pre-drug) and the day following drug (post-drug) appear above and below the drug day.

Seven male hooded rats, about 200 days old at the beginning of the experiment, were maintained at 80% of their free-feeding body weight. A standard two-bar Grason–Stadler operant conditioning chamber with one bar removed served as the apparatus. Reinforcement consisted of 45 mg Noyes food pellets.

The principal experiment lasted 8 weeks. Animals were run daily for 60 min, 5 days a week. The DRL 10 schedule was in effect throughout. Week 1 was used to collect baseline data (that is, no vehicle or drug); during week 2 vehicle-only injections were administered on the second, third and fourth days of the 5-day week; and weeks 3–8 were drug weeks. On drug weeks each of six rats received one of six doses, each in a different order (latin-square design). The seventh animal also received all six doses and was run as a spare. During drug weeks, the appropriate dose of THC was injected on the third day of the week with the vehicle being injected on the second (pre-drug) and fourth (post-drug) days. Sessions began immediately after injection. Doses were: 1.5, 3.0, 4.5, 6.0, 7.5 and 9.0 mg/kg intraperitoneally. Total volume of each injection was 1 ml. An additional 6.0 mg/kg dose was administered to all subjects during the week after the completion of the latin-square.

Because the results were extremely variable, all the cumulative records were rated qualitatively according to the following scheme: (M)—mescaline-like (Smythies's DRL hallucinogenic profile: that is, more or less normal rate of responding with one or more fairly long pauses between runs of responding); (A)—amphetamine-like (substantial rise in response rate with decrease in reinforcements); (B)—below baseline rate (decreased responding, but sustained throughout the session); (C)—cessation (complete cessation of responding or cessation for more than half the session); (N)—no appreciable change from pre and post-drug days. The reliability of our classifications was checked by an independent rater not involved in the experiment. Only two of forty-nine total ratings were found to be discrepant. Not only was there wide variation in the quantitative effect at each dose, but the pattern of responding, as explained later, varied markedly from one drug test to another.

Examples of response patterns taken from various rats given different doses during this experiment are shown in Fig. 2. The important point is that, although behaviour was disrupted in twenty-two of the forty-nine cases, the Smythies's hallucinogenic profile was evident in only four records (one rat at 3.0 mg/kg, another at 4.5 mg/kg and another at both 6.0 and 9.0 mg/kg). Even with these four records the correspondence with Smythies's data was not impressive: response rate between pauses was increased as shown in R3's drug record (Fig. 2). Of the remaining eighteen records in which disruption was apparent, two were classified as Bs, two as As and fourteen as Cs.

It might be argued that the 1.5 to 9.0 mg/kg dose range used in the present study was simply too narrow, and that we might have produced more of the so-called hallucinogenic profiles had we used a different range. This does not seem likely in view of the fact that one of the four most mescaline-like profiles was obtained with a dose of 3.0 mg/kg and another was found at 4.5 mg/kg. Also, some behavioural change was evident during many of the THC test sessions. In a preliminary study we found that doses of 12.0 mg/kg produced complete cessation of bar pressing on a variable interval schedule; in this study there was a tendency for overall level of responding to decrease with increase in size of dose.

To find the effect of the drug on total response rate, an analysis of variance was performed on the ratio of the total drug-day responses over the sum of the drug-day responses and the pre-drug-day responses. A score of 0.5 would indicate no effect of the drug; a larger score, that the drug increased the response rate; a smaller one, that it decreased response rate. Mean ratio scores in order of increasing dose from the six rats in the latin-square were 0.44, 0.41, 0.40, 0.50, 0.31 and 0.25. The second 6.0 mg/kg dose yielded a mean score of 0.49. Ratios based on post-drug-day scores were similar, indicating that there were no drug carryover effects. A latin-square analysis based on the response ratio scores yielded dose ($F=2.34$, d.f. = 5, 20) and animal ($F=2.40$, d.f. = 5, 20) effects approaching statistical significance (in each case, $0.05<P<0.10$). The fairly high F value across animals is probably because two rats were relatively unaffected by the drug. The drug effect can apparently be attributed to decreased performance at the two highest doses, an effect also found with the spare animal. There was no suggestion of a reliable effect across time ($F=0.74$), so an analysis of variance was completed with the ratio data from all seven rats. Mean ratio scores in order of increasing dose were 0.44, 0.42, 0.42, 0.51, 0.27 and 0.23. (The second 6.0 mg/kg dose yielded a score of 0.50.) The analysis revealed a significant dose effect ($F=3.93$, d.f. = 5, 20, $P<0.01$). Analysis of the linear and quadratic trends showed reliable effects ($P<0.005$, $P<0.05$, respectively) but these effects together accounted for only 73% of the variance. The high performance at 6.0 mg/kg probably accounts for the rest.

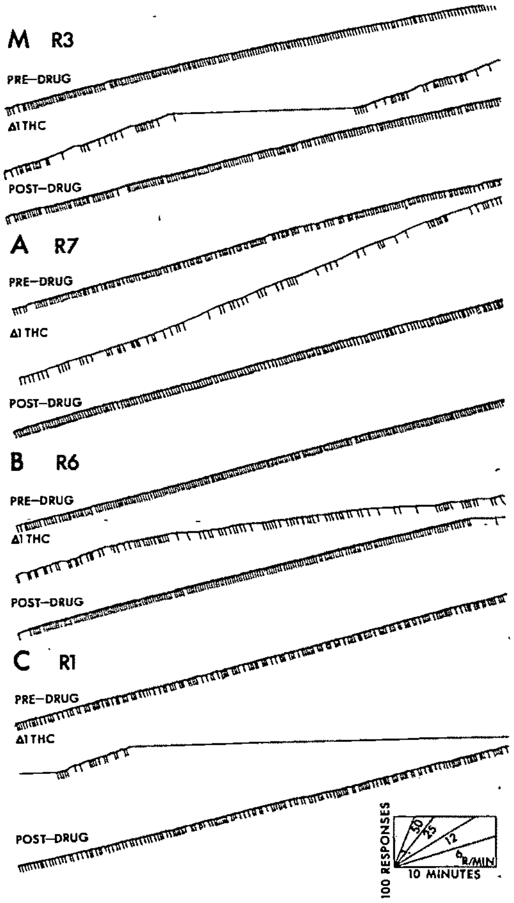

Fig. 2 Sample cumulative records portraying various response patterns under THC. Doses were 3.0, 6.0, 7.5 and 3.0 mg/kg for R3, R7, R6 and R1 respectively. See text for explanation of labels M, A, B, and C.

We decided to see if we could produce hallucinogenic profiles with mescaline. Accordingly, 2 weeks after the end of the principal experiment, all seven rats were given three 12.5 mg/kg intraperitoneal injections of mescaline spaced one week apart. The procedural details were identical to those already described except that saline was the vehicle. In sixteen of the twenty-one possible cases we produced Smythies-type profiles (Fig. 1).

Three weeks after the mescaline experiment, we administered a single 1.0 mg/kg intraperitoneal dose of α-amphetamine to five subjects. Except for one which did not respond at all, all rats had shorter IRTs[9]—the classic amphetamine effect on temporal discrimination.

The second procedure used was discriminated Sidman avoidance[10,11]. This schedule is described by referring to three time intervals. If the subject fails to respond in the response–signal interval a warning signal comes into effect and this marks the start of the signal–shock interval. If the animal fails to respond in the signal–shock interval a shock pulse is delivered at the end of that interval and the subject enters the shock–shock interval. During the shock–shock interval the signal remains on and shocks recur regularly. A response in the shock–shock interval terminates the signal and the response–signal interval is reinstated. All responses reinstate the response–signal interval to zero. Thus an animal may postpone signal onset by responding during the response–signal interval (premature responding); it may respond during the signal–shock interval (efficient responding) or, finally, it may respond in the shock–shock interval (late responding). After extensive training on this schedule, a subject concentrates its responses in the interval between signal onset and shock onset (efficient responding). The rat rarely delays pressing the bar until after shock onset (late responding) and only infrequently does it press before signal onset even though such responses are functional in postponing the onset of the signal and shock (premature responding). This discrimination can be disrupted by certain drugs: amphetamine increases premature responding and decreases late responding[11]; chlorpromazine increases late responding and decreases premature pressing[11]; and, according to Smythies *et al.*[12], hallucinogens such as mescaline, LSD-25 and N,N-dimethyltryptamine increase both premature and late responding.

The subjects were seventeen hooded male rats about 200 days old maintained at 300 g with water *ad libitum*. Twelve rats served in the actual experiment, five were predesignated as spares on the basis of their relatively poor (below 85%) discriminated avoidance performance before the start of the experiment. The apparatus consisted of three small operant-conditioning chambers each equipped with a lever, loudspeaker and white light bulb. A clicker together with the light was the signal. Scrambled shock could be delivered to the grid floor of the chamber from a Grason–Stadler shock generator set at an intensity of 1.0 mA. Shock pulse duration was 0.5 s. Response–signal, signal–shock and shock–shock intervals were set at 32, 8 and 4 s respectively.

All seventeen rats had received 130 h of training before the experiment and were avoiding more than 75% of the shocks. During the study each rat was run for two 5-day weeks with a 9-day rest between each experimental week. Half of the rats were run on weeks 1 and 3, half on weeks 2 and 4. The following routine was observed during the experimental weeks; rats were given a 30 min "warm-up" period on each day after which they were removed from the apparatus, and either handled or injected and then returned to the operant chamber. The duration of each session was 165 min, excluding the warm-up period. On day 1 of each experimental week the animals were handled, on day 2 they were injected with vehicle, on day 3 they were injected with vehicle or vehicle plus drug, on day 4 they were injected with vehicle, on day 5 they were handled. Doses of THC were 0.75, 1.5, 3.0, 4.5, 6.0 and 9.0 mg/kg THC. Two subjects were tested at each level. One of the spare rats received 0.75, two 4.5 and two 9.0 mg/kg.

There was a significant decrease in discriminated avoidance performance when drug day scores were compared with pre-drug ($t=2.66$, d.f.$=11$, $P<0.05$) and with post-drug ($t=3.32$, d.f.$=11$, $P<0.01$) scores. There were no significant vehicle effects.

Modified Bovet–Gatti profiles for the twelve rats in the experiment proper are shown in Fig. 3. In the majority of cases the profiles conform to those reported for other hallucinogens[12], that is, an increase in both premature and late responding, with a resulting decrease in efficient responses. Similar data were obtained from the spare rats. Examination of cumulative response records showed that, judging from the number of shocks received early in the session, onset of drug action was rapid. As the session progressed, premature responding increased and the subjects often failed to press in the presence of the signal. In most cases these effects persisted throughout the fairly long (165 min) session.

The THC effect was produced in both subjects tested with 1.5 mg/kg. This result, which we have repeatedly confirmed in subsequent experiments, shows that the discriminated Sidman avoidance schedule is sensitive to relatively low doses of THC. Even at 0.75 mg/kg the behaviour was disrupted in one of the two subjects.

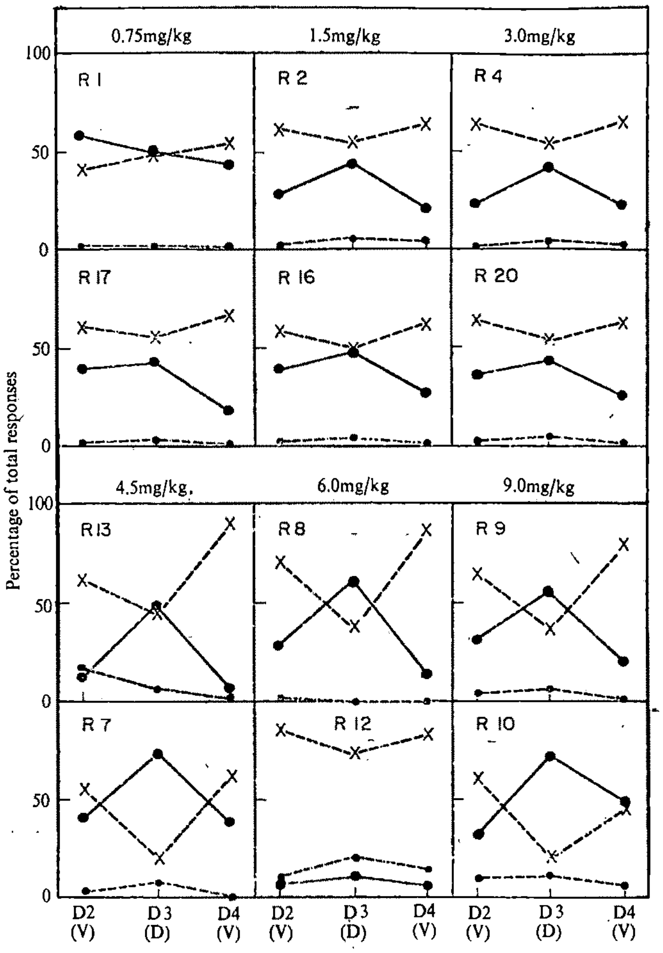

Fig. 3 Modified Bovet–Gatti profiles for twelve rats. Percentage of total responses made in premature interval (●——●), efficient interval (×- - -×), and late interval (●- - -●). Vehicle only (V) was injected on pre-drug (D2) and post-drug (D4) days; vehicle plus drug (D) on day 3 (D3).

An experiment of this design cannot be expected to reveal definite dose–response relationships. But preliminary analysis of the data from a more detailed (latin-square) study (described by M. D. W., C. D. W., and B. S. H. at the International Congress of Neuropsychopharmacology, Prague, 1970), although it confirmed the points made here, has failed to reveal any relationship between dose (within a 1.5 to 9.0 mg/kg range), and any of several measures of avoidance performance.

If a drug screening procedure is to be useful in the study of the effects of THC or other hallucinogenic drugs, it must be capable of reflecting subtle changes in behaviour at low dose levels and the particular pattern of change must be reasonably stable from animal to animal and from one drug test to the next. On the basis of the results of the first experiment, it seems that the DRL schedule does not meet either of these requirements when rats are used as subjects. With the discriminated Sidman avoidance schedule used in experiment 2, rats did show definite drug effects at low doses, and the drug effects were consistent with the main aspects of the Smythies-type avoidance profile for hallucinogens (increased premature and late responding). There was also an overall decrease in response rate only in the DRL situation. This underlines the importance of task variables and, so far, with rats, the discriminated Sidman avoidance baseline has proved to be more sensitive to THC than the DRL effects reported here. In conclusion, our findings run counter to Appel's[13] statement that positively reinforced behaviour yields more reliable psychomimetic effects at lower doses than does aversively conditioned behaviour.

Parts of this work were supported by research grants to G. C. W. from the National Research Council of Canada and the Ontario Mental Health Foundation. M. D. W. was supported by a Medical Research Council of Canada fellowship. Dr Raphael Mechoulam, School of Pharmacy, Jerusalem, Israel, provided THC. The steroid suspending vehicle was provided by the National Institutes of Health, Bethesda, Maryland. We thank Dr H. K. Kalant for helpful comments, Dr J. A. Carpenter for advice on statistics, and Michael Kocal for technical assistance.

Mechanism of Internal Stratification of Siliceous Sponge Spicules

BECAUSE sponges constitute an important part of many fossil records, their fine structure should be of interest to palaeontologists. Internal fine structure in spicule fossils would provide a valuable comparison with present day spicules. Furthermore, changes in the fine structure of spicule fossils may offer clues as to climatological or ecological conditions in that period.

There are two hypotheses to explain the appearance of concentric stratification of siliceous sponge spicules. Bütschli[2] contends that stratification is due to alternating layers of different refractility which he surmised is caused by a minute alveolar structure and, on the other hand, Schulze[3] maintains that the appearance of stratification represents lamellae of organic matter alternating with siliceous material. The evidence we report supports Bütschli's hypothesis of alternating layers of different refractility; but this difference seems to be caused not by minute alveoli but by periodically varying amounts of water. Schulze suggested that the concentric stratified structure is probably related to pauses in growth.

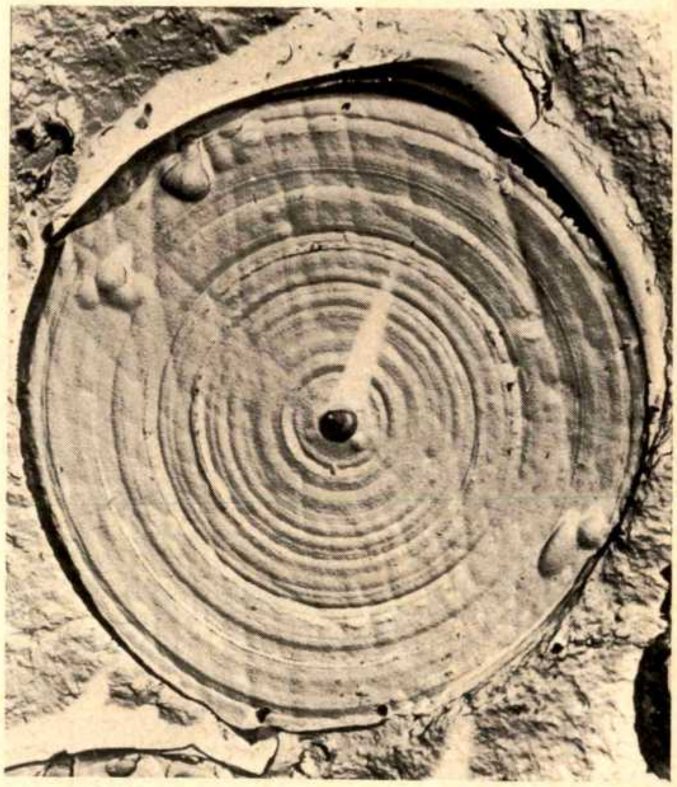

Fig. 1 Cross section of a spicule that was heated at 300° for 0.5 h then etched for 30 s in 5% HF. An extensive concentric ring structure is clearly discernible (× 8,000).

We propose that periodic pauses in the growth of a spicule permit the exposed siliceous surface to become highly hydroxylated. When growth resumes the hydroxylated surface becomes incorporated as a stratum of high etch sensitivity and low refractility giving rise to the concentric stratification revealed by electron and light microscopy[1–3]. We base this hypothesis on two new observations: first, the etch sensitivity is destroyed by heating above 300° (Fig. 1) but below 600° (Fig. 2); second, water (detected by mass spectrometry) is liberated from spicules during heating in that range (Fig. 3).

Concentric stratification is visible using light optics, but much of the detail is at or beyond the resolution of the light microscope. The following technique was therefore developed to study the fine structure of spicule sections in the electron microscope. Spicules from a siliceous sponge are embedded in epoxy resin. Sections are cut through the sample using a diamond saw so as to expose a maximum number of spicule transverse sections. The sawed surfaces are polished using cerium oxide and cleaned in an ultrasonic cleaner with distilled water. The exposed spicule surfaces are then etched in an aqueous 5% hydrofluoric acid (HF) solution for 30 s. Cellulose acetate replicating tape is used to prepare negative replicas of the etched surfaces. These are then shadowed at an angle ($\tan^{-1}$ 0.33) with platinum and carbon coated in a vacuum evaporator. Plastic is dissolved away with acetone in a vapour condensation washer and the replicas examined in a Siemens Elmiskop I.

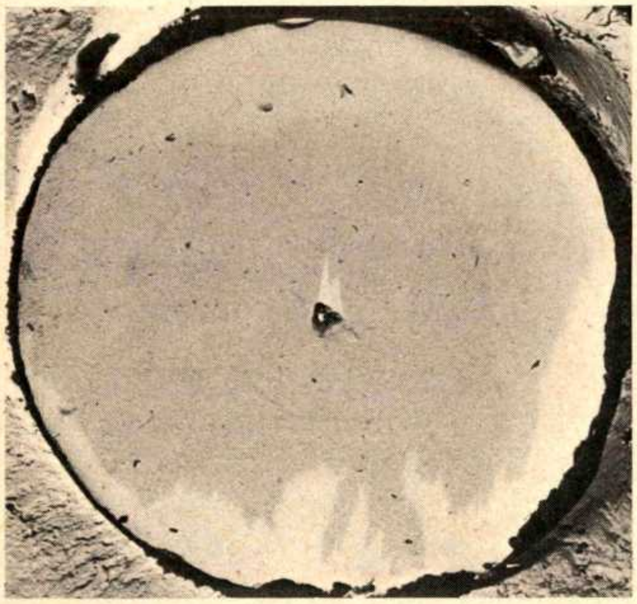

Fig. 2 Cross section of a spicule that was heated at 600° for 0.5 h. The ring structure has been obliterated (× 8,000).

Spicules are formed by specialized scleroblast cells. Growth is believed to be initiated around an organic filament and proceeds by apposition of constituent material[6,7]. Large siliceous spicules contain an axial filament which has been shown to contain protein[8]. Chemical analyses of *Acarnus* spicules indicate that there is enough organic matter present to account for the axial filament[1]. The siliceous material immediately surrounding the axial filament is more susceptible to HF attack than the bulk of the spicule. This causes the formation of a conical etch pit which in negative relief appears as a conical spire (Fig. 1). Even though the axial filament is resistant to HF attack, it is not usually preserved using this replica technique.

Fig. 1 shows a transverse section of the major macrosclere (a style ≃20 μm × 340 μm) from the siliceous sponge *Acarnus erithacus*. The replicas are negative impressions of the surface, so that any protrusions or depressions are reversed with respect to the original surface. There are several pronounced rings which probably correspond to those described by earlier investigators using light microscopy of fractured spicules[2,3]. Between these rings are many finer concentric impressions with spacings as small as 600 Å as measured in high magnification electron micrographs. Unetched spicule sections do not show any ring structure nor is any alveolar structure discernible[1].

Electron micrographs of spicules that are heated for 0.5 h at 300° show that internal structure is not appreciably altered by this treatment. Spicules heated for 0.5 h at 600°, however, no longer have a discernible ring structure (Fig. 2). Thus there seems to be a direct correlation between the loss of water vapour, or more specifically loss of inner constituent hydroxyls, and the obliteration of ring structure within the spicule.

The form of amorphous silica present in sponge spicules is probably that of silica gel[4]. Water content varies from about 6 to 13% corresponding to the formula $(SiO_2)_{2-5}H_2O$. Mass spectrometric analyses show that water vapour is evolved as spicules are heated (Fig. 3). The water peak (mass 18) rapidly rises between 300° and 400° and then drops off between 500° and 600°. Fripiat and Uytterhoeven[5], from studies involving infrared, thermogravimetric and chemical techniques, were able to distinguish among adsorbed water, surface hydroxyls and inner hydroxyls in commercially prepared silica gel. From these results they hypothesized that inner constituent hydroxyls are evolved at or slightly above 500°, whereas surface adsorbed water hydroxyls are evolved from 180° to 500°. This correlates quite well with our mass spectrometer data since the evolution of water vapour extends within about the same temperature range. Indeed it may even explain what appears to be two separate peaks in the mass spectrometer tracing. The initial peak probably represents surface adsorbed water and hydroxyls while the second peak represents inner hydroxyls.

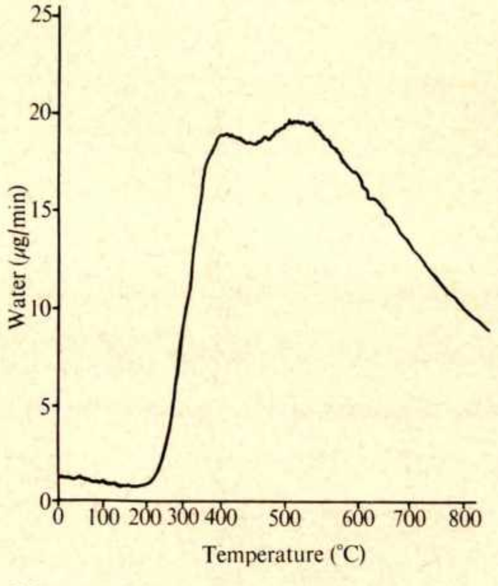

Fig. 3 Mass spectrometric tracing at mass 18 as the spicules are heated to show the evolution of water vapour.

We thank Dr J. Scala and Dr E. J. Hornyak for helpful suggestions and discussion. We also thank Dr R. K. Ware for mass spectrometer analysis.

BOOK REVIEWS

Biophilosophy

Biophilosophy. By Bernhard Rensch. Translated by C. A. M. Sym. Pp. xi+377. (Columbia University: New York and London, May 1971.) £5.65.

THIS is a valuable book. The author is a distinguished German biologist who has worked in neurology and behaviour studies but is chiefly known as a member of the small international group who made important contributions to the synthetic theory of evolution, his being on *Evolution above the Species Level,* the title of an earlier work available in English (Methuen, London, 1959). People who are interested will find his authoritative, lucid, and up to date discussion of this theory most useful, in particular his "100 rules of infra-specific and trans-specific evolution". This section justifies the volume, which is well translated from the German of 1968.

The greater part of the book presents the author's matured views on more general issues. Science must endeavour to start with absolutely certain facts and these are the mental processes which each of us is aware of within himself, resulting chiefly from perception. It is therefore essential to examine critically the process of cognition by perception, and this leads the author to the problems of mind/matter (he infers a "psychophysical substratum"), theories and laws, the causal analysis of organisms, and, briefly, free-will, ethics, and religion. Biology, in my view, cannot long avoid coming closer to grips with some of these issues and I expect that many biologists, such as those studying behaviour among others, will find Rensch's analysis helpful, whether or not they go the whole way with him.

Rensch explains that his views are developments of those of Th. Ziehen (1862–1950), and he calls his own attitude "realistic" and "positivist", in special senses which he explains. He infers proto-mental properties from early evolutionary stages onwards, and he assumes not one but many basic laws in physics and biology. As a philosopher Rensch is in some respects original; as an evolutionist he is orthodox and even, for an elsewhere cautious philosopher, a trace dogmatic on points where, clarity being lacking, certainty must be also. He repeatedly asserts the standard view that "random" mutations and the recognized selective processes can together account for the entire evolutionary process. But he does not, though writing in 1968, explain what "random" means or warn the reader that this central dogma lacks precision until the term has been analysed in the light of the recently acquired knowledge of organic structure, for example in molecular biology.

Adopting the author's own high intellectual standards, one wonders if it is not possible that when morphogenesis—important for evolution theory since selection acts on phenotypes—and the internal coordination and hierarchical structuring of organisms (stressed by him) are better understood, the current formulations of evolution theory may have to be improved to make them more precise and comprehensive. No orthodoxy is aware of all its assumptions, and few remain unchanged when a later generation brings these to light. Great advances often stem from the realization that what has been taken for granted is ambiguous in a new context. Should not a senior biophilosopher bear this in mind for the sake of his young readers to whom this task of clarification may fall?

LANCELOT LAW WHYTE

Memoirs of a Master

Wanderings of a Biochemist. By Fritz Lipmann. Pp. viii+229. (Wiley-Interscience: New York and London, May 1971.) £4.25.

JUST thirty years ago, in the first volume of *Advances in Enzymology,* Fritz Lipmann presented his classic paper on the central roles of energy-rich phosphate compounds and group transfer in biology. How he arrived at these ideas and how they have dominated biochemistry ever since is the central theme of his scientific memoirs in this charming book, his "wanderings".

Lipmann was trained in medicine with a view to going into general practice, but after his final examination he began to question the morality of patients purchasing their health, and doctors selling it. For this and other reasons he drifted away from medicine and returned to his home town of Koenigsberg in eastern Germany to attend the chemistry courses given in Meerwein's department. From there Lipmann moved to Otto Meyerhof's laboratory in Berlin in 1927.

Two strong personalities dominated the Kaiser Wilhelm Institute: Otto Meyerhof, a "spiritual presence" who engaged in "unwieldy muscle energetics", and Otto Warburg. The latter, on the top floor of the institute, had a mystery about him, but his "puritanical, pragmatic approach which rejected compromises and speculation filtered through to us from the fourth floor. He became our hero: his stern insistence on letting experiments speak and keeping interpretation to a minimum has dominated our generation". For three years Lipmann dabbled in the biochemistry of phosphorylated intermediates of metabolism, which included some of the hexose phosphates and creatine phosphate, and for this he gained his PhD. Then came a brief collaboration with Lohmann, who at that time had become the master of organic phosphates, classifying them by their very different susceptibilities to acid hydrolysis. Lipmann ended his "biochemical adolescence" with Meyerhof on some important experiments which demonstrated the direct connexion between muscle contraction and the breakdown of creatine phosphate.

The next two years were spent with Albert Fischer in Berlin, and at the Rockefeller University with Levene. In New York he turned his attention to a phospho-protein present in egg yolk and from it isolated serine-phosphate.

In 1932 Lipmann returned to Fischer, now in Copenhagen, as a component of the three big L's of Copenhagen: Linderström-Lang, Lipmann and Lundsgaard. Here he was able to prove that acetyl-phosphate was an intermediate in the oxidative decarboxylation of pyruvic acid and, further, that this phosphoanhydride is used for the enzymatic phosphorylation of adenylic acid. But then the European situation deteriorated and around the middle of 1939 the Lipmanns left Copenhagen for Cornell Medical School, New York. It was here in 1941 that, influenced by the significance of phosphorylation as found by Kalckar, Lundsgaard and others, he developed his ideas on the biosynthetic importance of phosphate derivatives and group transfer.

There are three main points in the review. First, organically-bound phosphates can be divided into two main groups: those with a low energy content and those with a high energy content or "energy-rich". Second, the energy-poor compounds are generally phosphate esters and arise by transphosphorylation either from an energy-rich or energy-poor phosphate donor. By contrast, energy-rich phosphates are derived by transphosphorylation from an energy-rich donor or by other means, such as oxidative phosphorylation. Third, these phosphorylated compounds, particularly those with high energy bonds, are used for biosynthetic purposes. Lipmann drew a distinction between these two kinds of phosphate bonds by introducing the famous "wriggle" or "squiggle" or ~P. Among several suggestions, he proposed that perhaps proteins are constructed by polymerization of amino acyl-phosphates: not correct, but not far off either.

The review elicited a very negative response from physical chemists, who regarded the whole concept as dilettantish. Nevertheless, for biochemistry as a whole it was a very major step forward. For the first time a clear distinction had been drawn between the energy requirements of biosynthetic and degradative processes.

Present-day job hunters should take heart: Fritz Lipmann had given a poor talk at an important meeting and, whether or not this was the reason, at this stage of his career he had difficulty in getting a position. Eventually he was accepted in the Department of Surgery at Massachusetts General Hospital, supported by a Ciba fellowship. Fired with high energy phosphate bonds, Lipmann now set out to show that his acetylphosphate was the universal acetylating agent. But hard as he tried, acetylphosphate did not do the job either in the acetylation of aromatic amines in detoxification, or in the formation of acetylcholine. This led directly to the discovery of a new cofactor, which he called coenzyme A (A for acetylation), in 1947. For this discovery Lipmann later received the Nobel Prize for Medicine.

The general thesis of active phosphates led Lipmann and his colleagues to discover such diverse compounds as carbamyl-phosphate in the synthesis of citrulline and of "active" sulphate, an anhydride of sulphate and adenylic acid (PAPS). Since then they have turned their attention to protein synthesis, being encouraged by their neighbours Hoagland and Zamecnik. Activated amino-acids turned out to be elusive, until Paul Berg found a novel form of active acetate, acetyl-adenylate. Subsequently amino-acyl-adenylates were identified as the true intermediates. During the past several years the Lipmann group, now at the Rockefeller University, has been largely responsible for characterizing the transfer factors needed in bacterial protein synthesis and how GTP is involved in the function of the ribosome.

Lipmann's book is divided into two parts separated by a series of personal photographs. In the first half he describes, often with delectable candour, some of the great scientists who impressed him and how he came to do what he did—a sort of scientific novel which contains a sprinkling of extracts from some of his early papers. The latter part of the book contains several more recent papers, including his Harvey Lecture, delivered in 1948.

Fritz Lipmann's seventieth birthday was celebrated at the 1960 Cold Spring Harbor Symposium on Protein Synthesis. The published volume contains a short appreciation of him which starts "There is no biochemist like Fritz Lipmann. He has always been at the heart of biochemistry". And that story, which should inspire the younger generation, is delightfully told in the *Wanderings of a Biochemist*. MARK S. BRETSCHER

Man Evolves

Man's Natural History. By J. S. Weiner. (The Weidenfeld and Nicolson Natural History.) Pp. xii+255. (Weidenfeld and Nicolson: London, April 1971.) £3.50.

FOR those who seek a broad view of the biological history of man, and a general understanding of the form and causes of human diversity, there is no better book than this new addition to the Weidenfeld and Nicolson Natural History series. Professor J. S. Weiner has pioneered the modern holistic approach to the study of man; more than anyone else he is responsible for the transformation of physical anthropology from a dry and dusty academic byway, as dead in ideas as the bones with which it was largely concerned, to its present focal position in the human sciences, with relevance to almost every aspect of human existence, and engaged with some of the most exciting scientific problems of today. Weiner's views are simply and well expressed in this book. The approach is an evolutionary one, which is surely the most appropriate for an overall consideration of man's natural history: evolutionary theory provides the integrating framework for human biology as it does for the study of other organisms, and profoundly influences perspectives both in the definition of issues and in subsequent consideration of them.

Weiner, in some detail, first compares man with other higher primates, principally to identify the major trends in hominid evolution, and traces the course of human descent as it is revealed in the fossil record. Here, perforce, attention has to be focused on skeletal material, but this is considered in functional terms, and wherever possible with reference to what is known or presumed about ecology and behaviour. In recent years, studies of living primates have revealed a vastly greater diversity of form than was previously suspected, and much of this, particularly as it is manifest in locomotor systems, is of focal concern, not only in considering the affinities of man with his closest relatives, but also in attempting to discover the factors for the emergence of the hominids, with their many distinctive features. Concurrent with this increasing interest in form, function and ecology has been a spate of both laboratory and field studies of Primate behaviour. It is still not at all clear how far these studies illuminate our understanding of the origins of human sociality, but few would object to the rather broad but insightful generalizations which Weiner makes.

Following the change from an arboreal to a terrestrial existence, man's ancestors adopted a hunting mode of life. These early terrestrial hominids were confined to tropical regions and probably hunted in the heat of the day, which no doubt explains the remarkable heat tolerance capacity of man. Weiner discusses the nature of this heat tolerance, along with the many other facets of adaptability which are to be found in human physiological systems, but, as here indicated, the viewpoint is ecological. Like other human physiologists he is concerned with the nature of physiological mechanisms, but unlike so many of his colleagues he is also concerned with the effects of physiological systems as they affect and are affected by the daily lives of people.

Weiner, as a physiologist, is also rare in having a deep understanding of genetics, and he discusses at some length in this book the factors which determine the genetic structure of human populations, and which cause geographical diversity in human genetic systems. He also brings together this understanding and his physiological knowledge in interpreting the anthropological history of the various peoples of the world, and never loses sight of the importance of cultural and technological factors, both in considering adaptation to local ecological conditions and in determining the broad course of human history. After all, *Homo sapiens*, in spite of his full range of biological capacity, was still a very rare species until the discovery of technologies which allowed crop cultivation and animal domestication. Today, of course, the problems facing the species are not of rarity, but of overabundance, and in a final chapter called "Towards a World Ecology", Weiner has something to say about this which all who are concerned with the human condition would be advised to read.

G. AINSWORTH HARRISON

Good Development

Developmental Processes in Higher Vertebrates. By R. Bellairs. Pp. xiv+366. (Logos: London, March 1971.) £6.

In this book the author provides a modern account of the development of amniotes, that is, of reptiles, birds and mammals or "the higher vertebrates". As far as I know no other similarly specialized treatment is available. For mammals, in particular, there are few general works, because the earlier stages of mammalian development are usually extremely hard to investigate. Most vertebrate developmental biology concerns the Amphibia which are constantly referred to, even in this book.

The first three chapters deal with general concepts; the fourth and fifth with topics special to birds; the sixth with embryonic inductions, mostly in the chick; the seventh and eighth with topics special to the early development of mammals and reptiles respectively; the final four deal with general problems, in particular the mechanisms and control of organ growth, teratology and immunology, and some of the molecular biology of development. I find this organization logical and very satisfactory from the point of view of one trying to understand developmental processes and their control rather than to assimilate experimental minutiae. As there is very little formal structure to the study of development the author is often forced to consider several conflicting explanations of the same process without being able to come to a firm conclusion, that is, she rarely finds it possible to reject an explanation on theoretical grounds. Indeed this reinforces the view that unifying principles such as Wolpert's "positional information" are vital to the development of embryology as a science.

The book contains an extremely useful, factual summary of many aspects of amniote development; it is surprisingly up to date, and it is accurate. The only failing lies in the lack of interpretation of some of the data presented, but I feel that the role of the book is really to stimulate thought and experiment, rather than to supply answers. Thus it should be useful to both theorists and experimentalists and can be recommended to all biologists.

Anthony Robertson

Connecting Neurones

Neurons and Interneuronal Connections of the Central Visual System. By E. G. Shkol'nik-Yarros. Translated from the Russian by Basil Haigh. Translation edited by Robert W. Doty. Pp. viii+295. (Plenum: New York and London, 1971.) $22.50.

This book was originally published in Russian in 1965 and has been revised and updated by the author for the English edition. Although entitled *Neurons and Interneuronal Connections of the Central Visual System* it is principally concerned with neurones of the visual cortical areas and, to a lesser extent, of the lateral geniculate nucleus. The neurones of these structures are described in considerable detail and several species, ranging from hedgehog to man, are examined. One is fascinated, page after page, to see the drawings of neurones which come in all shapes and sizes, from the well known pyramidal neurones to their less famous brethren, "the parasol" and "semilunar" neurones.

Although the author states somewhat towards the end of the book that "every architectonic characteristic, however trivial, corresponds to a different pattern of interneuronal connections", it is clear from the beginning that he is much impressed by cytoarchitectonic differences, and describes in some detail the different arrangement and types of cells in areas 17, 18 and 19 although it is not clear whose definition of areas 18 and 19, particularly for monkey and man, is used. This limits somewhat the value of the descriptions. It seems a pity that the author should not at least refer to the studies of Lashley and Clark and of von Bonin and Bailey. These authors, to varying degrees, failed to find the cytoarchitectonic differences so confidently described by Brodman (who is mentioned). Having described the cytoarchitectonics and Golgi picture of area 17 and (the undefined) areas 18 and 19, the author gains enough confidence to predict their connexions. For he states that "most association connections originate in areas 18 and 19, which follow from the neuronal structure of these areas ... while area 17 is connected principally with subcortical structures and the periphery. This conclusion is also supported by the narrowness of layer III of area 17 in primates". Such a statement may be received with some surprise, for the fact is, of course, that area 17 has abundant association connexions in almost all species described so far.

The most interesting parts of this book are undoubtedly the sections that deal with the structure, shape, dendritic trunks and axonal branchings of the individual cells, but the rigid criteria that we now demand as proof of actual "contact" between cells are, unhappily, missing. The Golgi method, on which the description is largely based, does not and cannot, on its own, allow the identification of interneuronal contacts. The author, for example, believes that axo-axonal contacts exist in the cortex and shows a very unconvincing Golgi photomicrograph to prove his case, although axo-axonal contacts have been extremely difficult to demonstrate in the cortex by electron microscopy and must be presumed to be very rare, if indeed present at all. Many other types of contacts are described, including connexions between spines and capillaries and axonal swellings and capillaries, almost all based on light microscopy. What was reasonable evidence in Cajal's day is not sufficient evidence now.

The book abounds in speculation, frequently based on scanty anatomical evidence. All the more pity, therefore, that precious little is said of "physiological" cells among which contemporary anatomists feel much more relaxed and at home than among "anatomical" cells such as the "cup-shaped" ones. Nothing is said about "simple" and "complex" cells, for example, although in a final chapter there is much speculation on colour vision as a function of the presence and shapes of specific groups of cells in the visual pathways.

This said, however, the book is bound to have some interest to students of the cortex, if only for the descriptions of the great variety of cells that make up the cortex. In the final analysis, all these different shapes of somata must mean something, just as much as the branching patterns and course of their dendrites and axons do. The book may also help to familiarize scientists in the West with Russian literature on the subject. Much of the material referred to in the book is apparently available in Russian only and therefore presumably unknown to most workers in the West. The highly readable translation will, it is to be hoped, remedy this situation, if only slightly.

S. Zeki

Hydronautics

Hydronautics. Edited by Herman E. Sheets and Victor T. Boatwright, Jr. Pp. xvii+454. (Academic: New York and London, September 1970.) £10.25.

Hydronautics is one of those recently-coined words which mean different things to different people. If aeronautics is the art of navigating in the air, then I would have thought that hydronautics should be the art of navigating in (and possibly on) the water: its etymology is certainly this. However, this book (to quote the preface) "treats the major scientific and engineering disciplines related to ocean technology". There are seven chapters each by a different author.

The chapter on ocean resources, by J. H. Clotworthy, is readable, well informed and includes some very sensible comments on potential exploitation. It covers the whole field from petroleum and fish to pollution (a "resource in reverse") and recreation. The only serious fault with this chapter is an almost complete lack of references, which is a pity since he so often succeeds in arousing one's interest in a topic, but having such a wide field can only deal with it briefly.

In the second chapter F. N. Spiess discusses the oceanic environment as it relates to information gathering and transmission interpreted rather broadly. About two-thirds of the chapter is devoted to acoustics, which is in proportion to its importance, but there are useful sections on electromagnetic systems (including light and infrared), gravitational variations and background radioactivity. This is another well written and informative chapter and it has a good bibliography.

R. L. Wiegel's chapter on ocean dynamics is a great disappointment in that it would be more appropriate to a research review than to a book on marine technology. For example, twenty-five pages are devoted to a scholarly review of the processes of wave generation, but only eighteen lines to the wave climate, which is possibly the most important aspect of ocean dynamics in relation to marine engineering.

The chapter on underwater navigation, by F. A. Andrews, devotes most of its space to acoustic position fixing, but has good descriptions of other navigational aids such as electromagnetic logs, inertia navigation systems and doppler-acoustic navigators.

Dealing with marine vehicles and structures, O. H. Oakley discusses the design of research and survey vessels, floating platforms and submersibles. This is a considerable part of the field of naval architecture, and in sixty-four pages means that the treatment is bound to be somewhat superficial. However, it is generally a good introduction to the subject with an adequate bibliography. An important omission is the absence of any discussion of the various modes of failure of pressure hulls.

The subject matter of sea systems by J. P. Craven and P. R. Stang largely duplicates that of other parts of the book, and in particular the previous chapter. One rather feels that "systems" is a popular word at present and that a chapter with this title had to be included even though the editors had no clear idea of what they meant by it. It is written in a pretentious style and adds little to the value of the book.

I am afraid that I have to admit to finding articles on policy generally a bore, particularly when they deal with the principles of planning. It is therefore possibly not H. E. Sheets' fault that I find his chapter on policy planning unreadable.

To sum up, the value of the good chapters in the book is such that they should be read by all students of marine technology, and it is a pity that the high price will stop most individuals from buying it. M. J. TUCKER

Particulate Systems

The Dynamics of Aerocolloidal Systems. By G. M. Hidy and J. R. Brock. (International Reviews in Aerosol Physics and Chemistry, Vol. 1.) Pp. xv+379. (Pergamon: Oxford and New York, January 1971.) £10; $27.

THIS book is intended to provide a broad introduction to a new series of reviews in aerosol physics and chemistry, and to be an up to date monograph on the subject of aerosol dynamics. Aerosol scientists who have worked in a field practically devoid of specialist literature until the advent of Fuchs and of Green and Lane (Fuchs, N. A., *Mechanics of Aerosols*; Pergamon, Oxford, 1964; Green, H., and Lane, W., *Particulate Clouds, Dusts and Smokes*; Spon, London, 1964) may find themselves overcome by the amount of literature now appearing, and the prospect of the regular appearance of further books in this series may seem rather daunting.

The chapter titles promise a comprehensive coverage of the subject, but more detailed reading gives the impression that while some topics are dealt with exhaustively, others get only cursory treatment. The scope and limitations of the book are honestly set out in the introduction, where the aim is given "to explore the dynamical behaviour of idealized aerosol particles in the light of modern developments in classical mechanics". Thus there is no reference to the effect of particle shape on aerosol behaviour and no mention of the important recent work of Stöber and others on this subject. This is a pity, for however intellectually satisfying it may be to provide theoretical treatments for the behaviour of spherical particles, they bear little relation to most real life aerosols.

Again, according to the introduction, the effects of electrostatic charging on the particles are taken into account, at least in an elementary fashion. But there is no mention of the charging mechanism or charge distributions or the now classical work of Bricard.

It is inevitable, although perhaps unfair, that this book will be compared with Fuchs and Green and Lane. It adopts a very much more theoretical viewpoint than either of the other two, and although experimental work is very frequently referred to, it is generally quoted quite uncritically and sometimes rather uninformatively.

It will therefore appeal to the theoretician rather than to the experimental physicist. This is perfectly acceptable, and no doubt the series as a whole will give a balanced view of the entire subject.

The errors I found were entirely in the indexing, for example, references to Green, H. and Grad, H. are mixed up. This is unimportant, but there is little excuse for the misspelling of a particular author's name everywhere it occurs.

W. J. MEGAW

Discrete Astronomy

Relativity and the Question of Discretization. By D. G. B. Edelen and A. G. Wilson. (Springer Tracts in Natural Philosophy, Vol. 20.) Pp. xii+186. (Springer-Verlag: Berlin and New York, 1970.) 38DM; $10.50.

THE possibility that objects of astronomical interest have a discrete structure has not been seriously considered by many workers in this field, presumably because there is no great body of evidence to support this view. The authors of this book, however—one a mathematician and the other an astronomer—take the minority view and argue for the possibility that the sizes of galaxies form a discrete sequence similar to that found for angular momentum in quantum theory. This they attempt from two different viewpoints, one theoretical and the other observational.

As the title indicates, general relativity provides the framework for the development of the theory in the first section. Consideration is restricted to EO galaxies since a definition of the idea of "size" for these presents fewer problems than for the non-spherical cases, though rather than use the radius to a surface where some physical parameter is specified the authors introduce the concept of a "jump discontinuity". This is physically identified with the surface where galactic space structure gives way to free space. A length scale is derived using this concept, and on the assumption that a parameter appearing in the derivation does not vary from galaxy to galaxy a sequence of possible sizes is obtained. The assumption seems to have no physical basis and to have been made for no reason other than that a discrete set may result, so one is doubtful of the conclusions drawn.

The second part of the book deals with what observational evidence there is to support their view, and starts by examining a sample of thirty-one galaxies for evidence of discretization. It is surprising and disturbing to find that of the two slightly different methods used to obtain linear diameters using redshifts as a distance indicator, one yields significantly discrete diameters and the other does not. Also a surprise is the apparent dependence of the minimum possible diameter on redshift, and an extension of the method indicates discretization of redshifts without being convincing.

The style of writing makes this book difficult to read and tends to obscure rather than clarify the issues. This is not a volume that I feel I should recommend. R. F. CARSWELL

CORRESPONDENCE

Scientists' Salaries

Sir,—There is already an attitude among administrators that because Fulton is beginning to have an effect professional staff (scientists and the like) can expect their highest rewards by transferring from their basic class to the administrative posts which may become available. (Four of the eight recently appointed Regional Managers in the Ministry of Agriculture were from the professional ranks.) This is surely to be deplored and resisted in that the most valuable scientists and technologists often have more to contribute in their professional work than in any transfer to administrative duties and should expect parity with their administrative colleagues which will now be lost if the present pay award is not altered by arbitration.

Secondly, I must mention a particularly mean action which is being proposed and so far has not been altered by negotiation. It affects a relatively few senior members of the former National Agricultural Advisory Service who transferred from colleges and county councils in 1946 to form the then newly formed service. They were given an undertaking that their retirement age would remain at 65 and this would thus partially compensate them for the loss of pension rights which they suffered in the transfer. (The years of employment prior to 1946 are only counting as half the years in calculating their retirement pensions.)

In the arrangements for the unfortunate reduction in the size of the service, those under 60 are being offered redundancy payments but those over 60 are to retire at once and are thus likely to lose up to five years of salary and 5/80 of their pension payments. The Ministry and, I understand, the Civil Service Department are saying that the undertaking given to these officers when they transferred from their former employment is not legally binding and that they will not therefore provide any redundancy payments for those compelled to retire between the ages of 60 and 65.

(Our correspondent wishes to remain anonymous.)

Baffling Brevity

Sir,—I refer to the conclusion of a letter about mercury pollution[1]: "We thank Dr Walter Olszewski, Buffalo General Hospital, for supplying the human brains."

Usually I would fully support your strictures[2] about superfluous acknowledgments, but here I feel that your readers must be left baffled by brevity. Are we to believe that Dr Olszewski has made a noble sacrifice to the cause of environmental improvement?—in which case the acknowledgments should surely be bolstered by the George Cross at the very least? Or is it that the authors of the letter are themselves not humans but computers?—a feat of programming for which Dr Olszewski might expect a large award from some electronics firm to supplement the meagre "we thank . . ." from his own creations.

Yours faithfully,

TOM CORREYBACK

Micrometeoroid Muddle

Sir,—I was very pleased to see our work on lunary microcraters and erosion phenomena mentioned (*Nature*; **231**, 492; 1971). Unfortunately, your geomagnetism correspondent fell victim to our unclear terminology. In addition, we were somewhat misquoted.

The terminology in question is the usage of the words "cosmic particles". Unfortunately, this term is in usage by workers in the field of "cosmic dust", "micrometeoroids", etc., as well as by people interested in cosmic and galactic particle tracks. No clear definition exists. In the first case it refers to *solid particles* of minute size. Particles in the 10^{-6}–10^{-13} g range of extraterrestrial or extralunar origin were described by many workers. In a broader sense the term refers to any solid matter of small grain size in space and therefore the term "cosmic particles" comes into usage. It is synonymous with "cosmic dust", "micrometeroids", etc.

In the second case the term "cosmic particles" refers to particles on an atomic scale, consisting of high energy radiation of solar or galactic origin, which are more commonly called "cosmic rays".

Over the past 6 months we have become increasingly aware of this problem of terminology and have recently decided to abandon the term "cosmic particles" completely in our work. Instead we use "micrometeoroids" and thus hope to avoid future misunderstandings.

In essence the difference is that of absolute size and/or mass coupled with vastly different flight velocities. Upon impact on a target, the "micrometeoroids" produce a minute impact crater and the "cosmic rays", due to their increased energy per mass unit, are capable of penetrating solid matter leaving characteristic tracks, *i.e.* lattice defects, etc. Thus both particle types are capable of doing damage to solid matter and are capable of mass removal. Both types of "particle" thus are lunar erosion agents. The quoted paper deals in an indirect way with the effectiveness of the two erosion mechanisms.

Our investigations quoted refer exclusively to phenomena of micrometeoroid impact. We have no data on cosmic rays, nor did we mention their effect on cosmic erosion. At the time of writing (August 1970), no such data were available. The main conclusion at that time was that the prime agent of lunar erosion is the mass removal due to micrometeoroid impact. "Cosmic ray" erosion seemed to be insignificant. Your correspondent misunderstood our reasoning and completely reversed our main conclusion. By now (July 1971), we have a somewhat better feeling for effect of the two erosion agents, and our statements in the *Earth and Planetary Science Letters* paper are substantiated.

Yours faithfully,

FRIEDRICH HORZ

National Aeronautics and
Space Administration,
Manned Spacecraft Center,
Houston,
Texas 77058

Our Geomagnetism Correspondent writes: Notwithstanding Dr Horz's willingness to take much of the responsibility for my misunderstanding, I must apologize to Dr Horz and his colleagues for making the error. My false sense of security was perhaps bolstered by their use of the term *primary* cosmic particles, for "primary" and "secondary" are, of course, adjectives used with specific meaning in cosmic ray studies. On the other hand, it is somewhat of an exaggeration to suggest that I reversed the main conclusion. The same ambiguity in the term "cosmic particles" also led me to suppose (wrongly) that Dr Horz and his colleagues were extending the term "micrometeorites" to cover cosmic rays. Nevertheless, in my interpretation of their conclusion I was careful to distinguish between "cosmic particles" (which I mistakenly called cosmic rays) and secondary ejecta from meteorite impacts—and this was surely the critical distinction, not that between the cosmic rays which were not considered by Dr Horz in the original paper and micrometeorites. Thus I do not think I misunderstood the authors' reasoning, only their terminology. In any event, this correspondence will have been useful if it leads to the avoidance of ambiguity in the future; and I am happy to have the record set straight.

Announcements

University News

James N. Butler, Tyco Laboratories Inc., has been appointed Gordon McKay professor of applied chemistry in the Division of Engineering and Applied Physics at **Harvard University**, and **Philip B. Tomlinson** has been appointed professor of botany.

The title of professor has been conferred on **Dr F. J. Weatherall**, Department of Medicine, **University of Liverpool**.

Dr J. Pitt-Rivers, Ecole Pratique des Hautes Etudes, Paris, has been appointed to the chair of anthropology, London School of Economics, and **Professor J. G. Taylor**, University of Southampton, has been appointed to the chair of mathematics at King's College, London. The following titles have been conferred within the **University of London**: professor of sociology, on **Dr P. S. Cohen**, in respect of his post at the London School of Economics; professor of biochemistry, on **Dr J. B. Pridham**, in respect of his post at Royal Holloway College; professor of chemistry, on **Dr J. H. Ridd**, in respect of his post at University College; professor of mathematics, on **Professor Herman Bondi**, in respect of his post at King's College; professor of bacteriology and immunology, on **Professor D. Gwynne**, in respect of his post at the Lister Institute of Preventive Medicine; professor of chemistry, on **Dr M. L. Tobe**, in respect of his post at University College; professor of nuclear medicine, on **Dr E. S. Williams**, in respect of his post at the Middlesex Hospital Medical School.

Mr V. R. Tindall has been appointed to the chair of obstetrics and gynaecology, **University of Manchester**, in succession to **Professor W. I. C. Morris**.

Dr J. J. Turner, University of Cambridge, has been appointed to the chair of inorganic chemistry at the **University of Newcastle upon Tyne**, and **Dr F. E. Hytten** has been appointed to a personal professorship in human reproductive physiology at that university.

Dr D. L. Gardner has been appointed to the Musgrave chair of pathology and to the directorship of the University Institute of Pathology in the **Queen's University of Belfast.**

Dr Findlay L. Swinton, University of Strathclyde, has been appointed to the second chair in chemistry in the new **University of Ulster**, and **Mr Malcolm Skilbeck**, University of Bristol, has been appointed to the third chair in education.

Appointments

Clayton R. Iverson has been appointed director-general of the **Defence Research Establishment Suffield** at Ralston, Alta., in succession to the late **B. J. Perry.**

Dr N. B. Kreitman has been appointed director of the **MRC Unit for Epidemiological Studies in Psychiatry**, at the Royal Edinburgh Hospital, in succession to **Professor G. M. Carstairs.**

Miscellaneous

Professor George B. Kistiakowsky, Harvard University, has been awarded the Priestley medal of the **American Chemical Society.**

International Meetings

August 26–31, **Stereology**, Berne (Anatomisches Institut, Bühlstrasse 26, CH-3012, Berne, Switzerland).

September 2–3, **Biochemical Society Meeting**, Brighton (Executive Secretary, The Biochemical Society, 7 Warwick Court, Holborn, London WC1R 5DP).

September 2–4, **Control of Human Ageing**, Rüschlikon-Zurich (John G. Cartwright, Gottlieb Duttweiler Institute for Economic and Social Studies, The Green Meadow Foundation, Rüschlikon-Zurich, Switzerland).

September 13–15, **Surface Chemistry of Oxides**, Uxbridge (The Assistant Secretary, The Faraday Society, 6 Gray's Inn Square, London WC1).

September 15–16, **Plastics in Medicine and Surgery**, Newcastle upon Tyne (A. F. Hall, North Eastern Section Plastics Institute, ICI Agricultural Division, Billingham, Teesside TS23 1LD).

Reports and Publications

not included in the Monthly Books Supplement

Great Britain and Ireland

Experiments in Participation. By George F. Thomason. Pp. 54. (London: Institute of Personnel Management, 1971.) £1. [16

Proceedings of the Royal Irish Academy. Vol. 71, Section B, No. 7: The Electronic Structures and Stabilities of Hexacarbonylchromium and Nitrogenpentacarbonylchromium. By William J. Chambera and Noel J. Fitzpatrick. Pp. 97–108. (Dublin: Royal Irish Academy, 1971.) 16p. [16

BP Statistical Review of the World Oil Industry 1970: Reserves / Production / Consumption / Trade / Refining / Tankers/Energy. Pp. 24. (London: British Petroleum Company, Ltd, 1971.) [26

Department of Education and Science. Education Survey No. 10: Potential and Progress in a Second Culture—a Survey of the Assessment of Pupils from Overseas. Pp. 38. (London: HMSO, 1971.) 30p net. [26

The Work of Aslib for the year ended December 1970. Pp. 33. (London: Aslib, 1971.) [26

Other Countries

Harmonizing Technological Developments and Social Policy in America. (Monograph 11 in a series sponsored by the American Academy of Political and Social Science.) Edited by James C. Charlesworth and Alfred J. Eggers, Jr. Pp. viii+247. (Philadelphia: American Academy of Political and Social Science, 3937 Chestnut Street, 1970.) $2. [185

South Australia. Institute of Medical and Veterinary Science—32nd Annual Report of the Council, July 1969—June 1970. Pp. 62. (Adelaide: Institute of Medical and Veterinary Science, 1971.) [185

Australia: Commonwealth Scientific and Industrial Research Organization. Report of the Division of Dairy Research for 1970. Pp. 47. (Melbourne: CSIRO, 1971). [195

US Department of Agriculture: Agricultural Research Service. General Catalogue of the Homoptera. Index to Genera and Species with Addenda and Corrigenda to Parts 1–17. Fascicle VI: Cicadelloidea. Compiled by Virginia Wade Burnside. Pp. 269. (Washington, DC: Government Printing Office, 1971.) $1.25. [195

HOW TO BUY NATURE

Volumes start in January, March, May, July, September and November, but subscriptions may begin at any time.

The direct postal price per subscription is:

12 MONTHS* (52 issues per title)

	Surface Mail UK and worldwide	Airfreight U.S.A.	Airfreight Canada
Nature (Friday)	**£14**	**$48**	**$52**
Nature+ Nature Physical Science	**£24**	**$83**	**$90**
Nature+ Nature New Biology	**£24**	**$83**	**$90**
All three editions	**£29.50**	**$108**	**$116**
Annual Index	**£1**	**$3**	**$3**

* Rates for shorter periods *pro rata* (minimum three months)

(Charge for delivery by air mail on application)

AUGUST 20 1971

Waiting for Lord Rothschild

A YEAR ago, the present British government was boasting of how it would differ from its predecessor by being good at management and by conducting its affairs openly, with ample discussion with interested parties before important decisions were arrived at. Nobody will forget that in the past year, the government has had a good deal on its mind. With luck, it may scrape into the European Communities, but Northern Ireland is likely to be a more durable distraction. That said, however, it is more than a little hard to understand precisely how the government hopes to rescue its reputation in its dealings with science, scientists and higher education. Certainly there is no sign of what used to be called open government. There is precious little evidence of the good management of which the government used to boast. If the issue were merely the government's reputation, of course, there are many who might consider that a fall from grace would do very little harm. The sad truth, however, is that several important matters are now being held up by the slowness with which urgent decisions are being made.

The way in which the Dainton report on the organization of basic science in Britain has vanished into limbo (see *Nature*, **232**, 287; 1971) is only one sign of the malaise. Mrs. Thatcher, the Secretary of State for Education and Science, has been telling the House of Commons for months that she would be able to make a decision on the future of the support for universites only after the University Grants Committee has completed its review of higher education. Not until the autumn, and only then with luck, will the first fruits (if that is the word) of Lord Rothschild's review of public expenditure on research and development as a whole begin to appear. And no doubt months will go by thereafter before all the uncertainties are resolved. Is it really now the government's intention to abolish the Atomic Energy Authority? What will happen to the research councils? Are they to be more closely integrated with each other and with higher education, or to be recreated in a new no man's land in between higher education and public service proper?

While no decision has been made and all the relevant documents are kept still unpublished, it is no wonder that there is widespread anxiety about the recipes for change which the government is devising. Certainly the way in which senior government scientists have been offered no pay award this year has been interpreted by many as a sign that there are harsher rods in pickle, and no amount of exhortation about the objectivity of the Pay Research Unit will convince the people concerned that their prejudices are misplaced. Most probably, people's worst fears will turn out to be illfounded, but that is only another way of saying that the government would have done a considerable public service if it had simply chosen to publish more of the raw material on which its decisions will eventually be made. If the Select Committee on Science and Technology wishes to redeem its most recent error—the scheme for setting up a special government agency to keep an eye on the growth of the British population (see *Nature*, **231**, 140; 1971)—it could do worse than go after Mr Heath's government for these inexcusable omissions and delays.

There are also policy decisions to be made, the simplest of which is one that might have been a gargantuan task as recently as a year ago—the refashioning of the machinery for administering what the government spends on basic research. This is what the Dainton report is all about. The questions with which it no doubt deals go deeper than how most efficiently to deal with the spending of £115 million a year (the present rate of expenditure) on university research and supporting facilities for university research in Britain and abroad, together with the miscellaneous collection of research projects more directly aimed at practical problems which are supported on the shoulders of the Agricultural, Medical and Natural Environment Research Councils.

In the first place, there is the question of how the research councils should be related to the other sources of university funds. For the past five years, it has been supposed that the object of the research councils should be to encourage in the pattern of university research a diversity which the necessarily egalitarian procedures of the University Grants Committee cannot provide. The policy has been succesful even though there is a chance that pure reason by itself might have worked wonders in some areas of research. Yet it is at least worth asking the question, in present circumstances, whether the research councils would not be more effective than at present if they were less directly concerned with the bread and butter of higher education, especially the support of postgraduate students, and more concerned to be highly discriminating grant-givers.

Next comes the now more familiar question of what should be the relationship of the research councils to each other. Is it really necessary to have four research councils working in the natural sciences, with another in the social sciences as well? Understandably, the people who operate the present machinery are always eager to describe its virtues, yet it remains a fact that important fields of research—whole organism biology, for example—have frequently fallen between the fingers of the two or three councils chiefly concerned. There is also the embarrassing conflict of philosophy between councils which consider that their chief obligation is to the universities and those who consider that they must "get things done", usually by the creation of intramural laboratories.

Over all these questions lies the crusty shadow of what is called the Haldane principle, the doctrine laid down by Lord Haldane during the First World War that there should be a kind of tension between those carrying out research within the government and those government departments likely to make the greatest use of the research. This is the spirit in which, first of all, the National Physical Laboratory was established as a kind of custodian of the then government's scientific conscience. At the time, the Haldane principle may have been a necessary simplification. After all, when research was still a novelty, there may have been good practical reasons for not spreading it too thinly. Now, however, the Haldane principle has outlived its universal influences. Good government departments—those concerned with transport and agriculture, for example, are ready enough to regard research as a necessary part of the machinery of government. Others, less imaginative, shelter behind the Haldane principle, which has become to them an excuse for doing comparatively little. It is no accident that the Department of Health and Social Security and the Medical Research Council between them carry out much less research of the kind likely to yield practical benefits in the operation of the health service than circumstances require. In short, this by itself is a sufficient proof that the time has come to abandon Haldane. Whatever Dainton may have to say on the relationship of the research councils to the universities and to each other, the chances are high that he will have recommended a shading of this ancient doctrine.

The government's relationship with industry is a continually vexed question. Over the years, the government has accumulated a whole string of anomalous policies. The research associations, the darlings of the early fifties, are now considered pariahs. The National Physical Laboratory, intended in an earlier age to stimulate industrial innovation, has settled down to quite a different task. The recommendations of the Trend committee in the early sixties, echoed by Mr Anthony Wedgwood Benn in his scheme for reorganizing his research and development establishments, that there should be independent research and development authorities for different fields of industrial activity, is also now a dead letter. In circumstances like these, it must be exceedingly tempting for somebody like Lord Rothschild to seek an entirely novel formula for helping to stimulate industrial innovation by the sensible use of public money.

By good chance, Lord Rothschild should know that there are many ways in which the job could be done. One of the most important is to find some way of helping to make it seem to commercial enterprises that spending money on research and development is in the long run profitable. How is this to be accomplished? One necessary change of direction is that companies should be persuaded not merely that the manufacture of a successful typewriter, for example, may be more important than the manufacture of an unsuccessful aircraft engine but that research and development have as important a contribution to make to the former as to the latter. Exhortation might help, but the precedents for this are few. Taxation (or the amelioration of it) might also help. Government purchasing, by selectivity and even its willingness to go abroad, could have an important influence on the zeal of British enterprises. In the long run, however, example is what matters most.

Should not Lord Rothschild in his Jovian view of British science examine one field from which his predecessors have usually been excluded, either by design or cowardice—the nationalized industries? At first sight, at least, too many people are doing far too little research in the nationalized industries, even though these are publicly owned. The cost of this neglect is well typified by the scandal of the broken down generating sets in the United Kingdom two years ago. To bring about a better climate for research and development in this important field would be valuable in itself, an important example to other industries and also a way of using a stock of talent which seems to have become an embarrassment to the politicians.

Higher education is also being quickly muddled, not so much through malevolence as indifference. Two weeks ago, Mrs Thatcher announced in the House of Commons her decision that the polytechnics would be given extra funds to help with their development, a step which in itself is wise and even humane, for the polytechnics have a long way to go to whatever goals they and Mrs Thatcher, in their several ways, consider to be justifiable. The trouble is that nobody is quite sure what strategy the government has for the development of the polytechnics and for their relationship with the universities on the one hand, and the colleges of education on the other. Is it, as it might be, that pushy polytechnics will in future be encouraged to usurp the position of the weaker universities in the academic pecking order? Is it, alternatively, that Mrs Thatcher was trying her best to make a virtue of necessity in much the way Mr Anthony Crosland was forced to make the best of a *fait accompli* when he first argued the case for what is called the binary system of education in 1964? Here again, perhaps, Mrs Thatcher is being compelled to wait for the report of yet another committee—Lord James's inquiry into the education of teachers. The trouble is that by continuing to spend public money on higher education without doing the government's essential job in the formation of policy, Mrs Thatcher is creating a set of circumstances from which nothing but disappointment can spring.

This is one field in which the Rothschild inquiry could help to unlock the log-jam in which important decisions seem to be imprisoned. It is only fair to say, however, that his influence will be diminished if he cannot find some way of simplifying and making intelligible the machinery at present used for making the decisions that seem to elude him. Over the years, the decision-making apparatus has grown by accident. The research councils are said now to know more clearly where they stand than under the previous government, but there is a fuzzy line between them and the University Grants Committee alongside them and the Council for Scientific Policy above them. But in any case, the council is merely advisory, as was Sir Solly Zuckerman's old Advisory Committee on Science and Technology, a body apparently distinguished by the irregularity with which it met. Scientific advisers abound—Sir Alan Cottrell in the Cabinet Office has replaced Sir Solly Zuckerman, who nevertheless has stayed on as an occasional consultant. The Ministry of Defence has its own apparatus for devising policy on research and nobody quite knows how all of them are subservient to Lord Rothschild's office, the nearest thing in Britain to the Office of Management and Budget in the United States. The consequences of this complicated and ill-defined structure are apparent in complaints like this. Although it is by now apparent that the British government habitually loses a great deal of decisiveness by its failure to be open with its constituents, it is also true that in the management of its policy on research and development, the machinery that exists is a hindrance, not a help. If ever the tablets on which Lord Rothschild is supposed to be working are brought down from the mountain, this is the first thing to be written on them.

Ducks and Drakes

IT is to be hoped that only pre-Keynesian bankers will be dismayed at the discovery that it has been necessary to restrict the convertibility of the United States dollar. Elsewhere in the world, there is plenty of recent experience to show that the most upright and high-minded people can survive the shame even of devaluation, a much more conspicuous way of passing over the claims of creditors than the package announced earlier this week in Washington.

To be sure, there are two other components of recent memory that will make those outside the United States uneasy. First of all, draconian as Mr Nixon's proposals may appear, they resemble all too closely the kinds of stratagem that British Chancellors of the Exchequer have been forced to use in the past few years in the attempt to avoid full-scale devaluation, so that even those who wish Mr Nixon well may be tempted to hedge their bets by converting whatever dollars the system will now allow. The second vivid memory is the histrionic quality of what is called the crisis through which it is now said the world is passing. If reason has any place in monetary affairs at all, events of the past week are most of all remarkable not because it has been necessary to hedge about the relationship between the dollar and other currencies but because the United States has been able to keep on buying gold at one ounce for $35 for more than a quarter of a century. How can it be that a numerical relationship established in 1946 at a remote village in New Hampshire should have persisted so long?

The first thing to be said is that the relationship between gold and the dollar has been in itself artificial. President Franklin D. Roosevelt is said to have left the gold standard in the early thirties, but nobody really knows what that means. Each decade there seems to be another crisis of conscience in the United States, and each time there seems to be a reaffirmation of the view that gold and the dollar must (at some price) be at one. The affection of the United States for gold is, of course, a powerful stimulus of the gold-mining industry but in reality the objective is not so much to provide an absolute monetary standard but rather to relate the prices paid in dollar bills for commodities imported or exported to a quantity of material which can be reckoned to have a fixed value on a time scale which is longer than the interval during which commercial transactions between nations are settled. In other words, the function of the relationship between the dollar and the price of gold has been to provide a yardstick by means of which currencies might be converted. Its disadvantage has been that stocks of gold, sometimes many times the nation's Gross National Product in value, have also been given their face value.

What can scientific research and development contribute to a solution to this problem ? The most obvious device would be relating the value of the dollar not to gold but to some naturally radioactive material, preferably one with a lifetime comparable with the lifetime of a human generation (so that hoarders would not feel too cheated) but not so great that jackdaw nations could dominate the international monetary scene to a degree not matched by their current economic performance. (In some quarters, it will be a shock to know that strontium-90 appears to have a suitable lifetime.)

These, however, are devices which share with the monetization of gold the defect of being symbolic. Why not instead seek means by which currencies are converted into each other at rates determined by the current economic performance of the countries concerned but smoothed out over an interval of time (say three months) so that commercial transactions would not be seriously impeded ? By now, the economic textbooks are thickly peppered with proposals of this kind, some of them known by the unedifying name of the crawling peg. It is almost beyond belief that in a world which chooses to rack its conscience regularly on the issue of whether the profession of science is sufficiently responsive to social needs, economists and bankers should be allowed such licence as they assume in the handling of the international exchanges. At this point, few people may be able to guess how much gold to swap for dollars three months from now, but it is a near-certainty that by then each ostrich will once more have buried his head firmly and, he hopes, permanently in the sand again.

100 Years Ago

CLIFTON COLLEGE SCHOOL OF NATURAL SCIENCE

The accompanying is one of these fortnightly papers :—

MAGNETISM

1. Soft iron can never be permanently magnetised, yet a piece of soft iron in contact with a magnet becomes a magnet. Why ?
2. What do you understand by *coercive force*, and magnetic *saturation ?*
3. How is magnetism influenced by heat ?
4. Mention the substances which are attracted by a magnet in addition to iron.
5. State one or more of the methods by which steel bars may be magnetised.
6. What is the *declination* or *variation* of the magnetic needle, and the present extent of it?

CHEMISTRY

a. For First and Second Sets, Modern Side only.

1. Mention the oxygen compounds of phosphorus, and the action of water upon them.
2. Give an account of arsenicum and its chief characteristics.
3. What are the constituents and characteristics of arseniuretted hydrogen ?
4. What is "white arsenic," and how may it be prepared ?
5. You are given a liquid suspected to contain arsenic ; by what means would you examine it ?

b. For all other Forms.

1. Ammonia gas, and hydrochloric acid gas, are brought into contact : what is the resulting compound, and to what may it be compared ?
2. What is *ammonium ?* Describe the formation and appearance of ammonium amalgam.
3. What do you know of chloride of nitrogen ?
4. What is nitric acid, and by what means may it be procured ?
5. State the action of nitric acid upon metals,—copper, tin, antimony,—and the general tendency of the acid.

From Nature, 4, 329, *August 24*, 1871

OLD WORLD

CENSUS RETURNS

Malthus Fulfilled

PRELIMINARY returns now published suggest that the population of the United Kingdom is growing less quickly than was expected as recently as 1968 (*Census 1971 England and Wales. Preliminary Report*. HMSO, £0.60). The first figures show that in April this year, the population of the United Kingdom was 55.35 million, an increase of 2.64 million or 4.9 per cent since the previous census in 1961. If this preliminary figure is to be relied on, it suggests that there has been no net growth of the population of the United Kingdom since 1968 when, in evidence to the House of Commons Select Committee on Science and Technology, the Government Actuary in the Registrar-General's Office quoted forward projections of the population with 1968 as base year with an actual population of 55.4 million. At that point, it was estimated that the population of the United Kingdom would grow more or less monotonically by about 350,000 a year until 1980. If the growth seems not to have materialized, it will invalidate either the forward projection of the British population or the method used for counting it. For what the figures are worth, the 1971 census suggests that the population of England has risen by 5.4 per cent, that of Wales by 3.0 per cent and that of Scotland by a mere 0.9 per cent. It is something of a surprise that over the decade, Northern Ireland should have the highest growth rate at 6.8 per cent.

There are few surprises in the report, although there are shifts of emphasis from 1961. The fastest growing region in the ten years was the belt from the North Midlands through Leicestershire and Peterborough to the Solent, which coincides with a slackening growth rate in the home counties. A number of local authorities have roughly doubled their population in the past ten years, several in the belt from the Midlands to the Solent.

Coinciding with the drop in the south, West Suffolk and Huntingdonshire become the fastest growing counties with increases from 128,918 to 164,201, and 159,175 to 202,337 respectively. Essex has the biggest single population leap—now 1,353,564, a gain of some 250,000—mostly overspill from London.

The figures also indicate a draining away of population from the centres of large cities—Liverpool shows a loss of 20.4 per cent over the ten years and Manchester 19.9 per cent. Although Greater London has the highest net loss of 613,429, as a percentage it is only 7.9 per cent. All seven of the largest cities in England had population drops. In the conurbations, however, the drop is less marked—on Merseyside for instance it is only some 8.8 per cent—which suggests that people are moving into the suburbs and surrounding towns of large cities.

The population in the extreme North of Britain decreased, with Lancashire, Cumberland and Northumberland all returning figures lower than in 1961, and Durham showing the smallest percentage growth of any county.

Wales still claims the most thinly populated areas of either country, with Montgomeryshire, Merionethshire and Radnorshire not only the least populated counties but also those with the lowest density of population per hectacre. The population in the ex-coal valley of the Rhondda fell while the population in the Welsh urban areas fluctuated—Cardiff and Merthyr Tydfil fell whereas Bangor and Swansea grew in numbers.

SCIENTISTS' PAY

Tribunal Tribulations

THE Institution of Professional Civil Servants and the Civil Service Department presented their respective cases to the Civil Service Arbitration Tribunal on Thursday August 12. This was the first time that the two sides had come together since negotiations were broken off on July 2.

The IPCS entered the tribunal riding high on the success of their protest meeting at the Central Hall, Westminster, two days earlier when more than 3,000 scientists from all corners of Britain came to support the institution's case. The Civil Service Department has remained unmoved by all the protest meetings that have been going on since early in July and its offer and the arguments that substantiate it have remained unchanged.

The substance of the government's offer to more than 17,000 scientists, was given in detail in *Nature*, **232**, 434; 1971, together with the IPCS's counter claim. The government offered no increase to the higher grades—Principal Scientific Officers, Senior Scientific Officers, Chief Experimental Officers, Senior Experimental Officers and Experimental Officers—and only a small increase to the other scientific grades well below that demanded by the institution. The attitude of the IPCS to this offer was shown in their submittal to the tribunal which states, "members are bitterly resentful of an 'offer' which gives no increase to many, and little to others at a time when the cost of living has risen substantially, and when other groups of employees in the public and private sectors have received substantial increases".

Mr William McCall, General Secretary of the Institution of Professional Civil Servants.

The Civil Service based its offer on the result of an independent pay research inquiry into the salaries of scientists both inside and outside the Scientific Civil Service, whereas the IPCS would have liked greater emphasis placed on internal relativities within the Civil Service. The government made its position clear in its submission. "The Official Side does not accept that it is necessary, or that it would be appropriate, to resort to horizontal relativities as a primary or even a major consideration in determining the pay of the scientific grades on this occasion

—Photograph by Mark Gerson, FIIP, ARPS.

Rt Hon. the Earl Jellicoe, Minister in charge of the Civil Service Department.

". . . we are satisfied that the comparisons established by the (Pay Research) Unit are fair and accurate, and that they provide solid evidence on which to base the pay of the scientific grades".

The IPCS countered this by saying that "Pay Research provides an inadequate and unreliable basis for the determination of pay of scientists in the Civil Service because (1) of the quite different circumstances relating to the aims, functions, organization and staffing policies between research and development in government and in industry ; and (2) the pervasive influence of the government (by far the largest single employer of scientists) on the pay of scientists in industry vitiates fair comparisons. The institution therefore considers that the pay of scientists should continue to be based solely on internal relativities."

These statements emphasize the extent of the differences between the parties. The institution pressed for the use of internal relativities to determine salaries and advanced several arguments that purported to show that pay research has several shortcomings when used in the present context. These arguments were chiefly based on the different career patterns of the government scientist and the scientist in industry. Among other factors, this results in significant differences in the ages of people doing similar jobs; for example, the equivalent of the Principal Scientific Officer in industry is nine years younger than his counterpart. The Civil Service tribunal announced their decision on the pay of government scientists on Wednesday. The overall result is a compromise between the increases asked for by the IPCS and that offered by the Civil Service Department. There will be an increase of 5% to all those classes not offered anything in the original offer. Mr. McCall described the award as deplorable.

BOX GIRDERS

Yarra Disaster

THE report of the Royal Commission into the lower Yarra river bridge disaster, published in Australia last week, has apportioned the blame for the disaster among the consulting engineers, the contractors and the bridge authority. The direct result is that the joint consulting engineers Freeman, Fox and Partners of London, and Maunsell and Partners of Melbourne, have been dismissed. To complete the bridge, the Lower Yarra Crossing Authority has instead appointed a team of engineers under its direct control. Dr W. A. Fairhurst, of W. A. Fairhurst and Partners of Glasgow, will head the team, and a company spokesman said on Tuesday that Dr Fairhurst will be involved as an individual and that the company will not be directly involved.

The commission's report sets out the series of events that led to the tragedy on October 15, 1970, when 35 people lost their lives. A gap of several inches was found between sections 10 and 11 of the west side of the bridge when they were fitted together, and the report states that difficulty in getting the two half girders to the correct relative position "without doubt was due to the fact that the camber curves on the two halves were different not only in amplitude but in the shape of the curve, so that even when connexions had been made at a number of diaphragms it was still necessary to use large forces to make the remaining parts fit."

The large force in this case was applied by means of 80 tons of concrete blocks raised onto the bridge. On September 9, 1970, a buckle was observed and the report says "there can be no doubt that the act of adding the kenteledge"—that is the concrete blocks —"was the precipitating cause of the buckle. . . . The buckle was a clear indication that partial failure of the structure had occurred. The margin of safety against complete collapse must then have been small".

The collapse occurred after an attempt to straighten the buckle on October 15. Previously a buckle had appeared in sections 8/9 on the east side of the bridge, and this had been successfully dealt with in a similar way to the ill-conceived sequence of events that took place on sections 10/11 on the west side. The objective was to remove a series of bolts and so alter the distribution of stress in the buckled structure. The commissioners sum up what followed by saying ". . . a dramatic change took place. First, the vicious buckle, which up to that stage had been limited to the inner and upper panel, spread into the adjacent two upper panels. This was accompanied by the buckling failure of the upper part of the inner web plate." The report goes on to say "from that time onwards the north half span had inadequate strength to sustain its own weight, and only survived because it was able to bear down on to the south half through the interconnected transverse diaphragms." The collapse of the bridge occurred 50 minutes later which the commissioners feel was a surprisingly long time in the circumstances, and they suggested that ". . . a small increase in safety margin might have made all the difference".

The plans and calculations of Freeman, Fox and Partners come under close scrutiny in the report, which says that "the calculations contain a great many errors of arithmetic and of engineering principle and these have gone unchallenged until this commission". The commissioners also stated that "they could not agree with Freeman, Fox and Partners' witnesses that "the design, as it now is, is unquestionably sound". Perhaps the most damning criticism is the following quotation from the report: "We reject . . . claims of non-culpability by Freeman, Fox and Partners, and find it hard to believe that those who made such claims can themselves believe them to be true". The report goes on to say ". . . a basic cause of the tragedy . . . was the design inadequacies which led to the safety margins being much too low and certainly lower than the specified values".

Freeman, Fox and Partners in their London office are silent about the report, although Sir Ralph Freeman, one of the senior partners, has been reported in a speech from Melbourne as saying that he categorically denies that the design of the west gate caused or contributed to the collapse. Sir Ralph also stated that he felt that none of the serious allegations made against his firm was well founded.

Indeed the Royal Commission's report and conclusions are the work of three men—Sir Hubert Shirley-Smith, Mr Justice Barber and Professor Bull—and there will be many differing views and opinions on the facts. It is, however, gratifying that a full report has been published. Although a bridge with a similar design collapsed at Milford Haven in June 1970, the whys and wherefores have yet to be made public.

The aspect of this disaster and report which will be of most concern to engineers in Britain is whether it will have any effect on the ability of British firms to bid for contracts abroad. A spokesman at the Institution of Civil Engineers said this week that he did not believe that the report would have any adverse effect. Only time will tell whether this is so.

ATOMIC ENERGY

Aldermaston March

THE Executive Committee of the British Society for Social Responsibility in Science has come out against the decision to transfer the Atomic Weapons Research Establishment at Aldermaston from the UK Atomic Energy Authority to the Ministry of Defence. In a statement issued earlier this week, the committee says that it is opposed to any steps to increase the size of the British defence establishment. It also argues that there are potential dangers in giving a single minister responsibility for the manufacture of nuclear weapons and for planning the strategy for using them. The statement goes on to say that under the new arrangements, it will be hard to encourage the recent tendency to divert the energies of the Aldermaston establishment to civil work, and that the publication of results not necessarily of military importance will now be impeded. It singles out for special mention the seismologists at Aldermaston who may be less valuable members of the British scientific community after being transferred to the Ministry of Defence. The committee complains that Mr John Davies, the Minister at the Department of Trade and Industry, has been "guided solely by administrative convenience" in accepting the recommendations of the Rayner committee that Aldermaston should be transferred to the Ministry of Defence, and asks him to change his mind before it is too late.

The Atomic Energy Authority confirmed earlier this week that the seismic unit at Blacknest, Aldermaston, is indeed to be transferred to the Ministry of Defence. Some of those connected with the work of the unit are confident that the transfer will entail no impediment to the free dissemination of the results of the work not directly of military significance. If there is anxiety at Aldermaston, it consists more of a fear that the Civil Service proper will be a less stimulating environment for creative work than the Atomic Energy Authority has provided. A more sombre speculation now coming to the surface is that the decision about Aldermaston, following as it does on the separation of those parts of the Atomic Energy Authority responsible for the manufacture of fuel elements and nuclear fuel, and also radio-isotopes, has left the government with very little option but to abolish the Atomic Energy Authority as such and to set up the Atomic Energy Research Establishment at Harwell as a self-contained concern as free to go its own way as any government establishment can hope to be.

FOUNDATIONS

Drawing in of Horns

THE Smith Kline and French Foundation, one of the smallest and newest of the sources of scientific funds in Britain, has been forced by rising costs and encouraged by recent successes to modify its policy on grant-giving. In the eighth Annual Report, now published, the foundation says that it will in future increase the maximum for an urgent grant from £500 to £700, even if this means that there will be less to spend on more deliberate applications of somewhat larger sums. The foundation has been spending close on £25,000 a year for the past eight years, and specializes in comparatively small equipment grants, of which eighty-one were awarded last year.

The foundation, whose trustees are Professor F. G. Young, Professor D. A. K. Black, Dr W. A. M. Duncan, and Professor Sir Ashley Miles, was set up in 1961 to dispose of funds donated by Smith Kline and French Ltd, principally for research with a medical bias. The grants, which do not exceed £2,500, are made to individuals working in universities, hospitals or technical colleges, and are most often spent on items of equipment. Ninety per cent of the grants in 1970 were to new applicants, who are given priority over applicants who have received grants before.

The foundation aims to provide for research which could not expect help from public funds, which is presumably the reason for the virtual absence of the two great medical fields of cancer and immunology from the list of research projects assisted in 1970. Five of twenty-eight recipients are working on various cardiovascular problems, but otherwise the range of fields covered is extremely heterogeneous, extending over the role of dopamine in locomotor control, endocrine function in sleep and the biosynthesis of mycobactins.

CONSERVATION

Royal Society at Aldabra

A SAFE future for the Aldabra atoll seems to be assured at last. The Royal Society has bought a fourteen year lease of this unique group of coral islands in the Indian Ocean and will pay only a nominal rent to the Commissioner of the British Indian Ocean Territory.
